9.34. Geometry Data Types and Spatial Index Support

Virtuoso includes a spatial database capability from version 6.01.3126 onwards. This capability is specially geared towards geographical data in RDF but can be used with SQL also. The functions implemented follow the SQL MM spatial specification where applicable but the entire SQL MM function set is not supported.

Spatial indexing is supported by a two dimensional R tree implementation. The geometries supported may have from two to four dimensions, with a choice of WGS 84 (or similar) latitude and longitude coordinates with haversine distances or a flat 2 dimensional plane for spatial reference system.

9.34.1. Spatial References

The default reference system is WGS-84 with coordinates in degrees of longitude and latitude on Earth. The SRID number for this is 4326 and is assigned by default to all new geometries. `ST_Transform` can be used to re-calculate coordinates of a shape from one spatial reference system to another. `ST_SetSRID` can be used for altering SRID without altering coordinates.

Distances and precisions for "latitude-longitude" spatial reference systems are in kilometers, as approximately calculated with the haversine formula. For other systems they are in the same unit as the coordinates.

9.34.2. Geometric Objects

Virtuoso supports a wide variety of spatial features that can be represented in WKT or SHP: BOX, BOX2D, BOX3D, BOXM, BOXZ, BOXZM CIRCULARSTRING COMPOUNDCURVE CURVEPOLYGON EMPTY GEOMETRYCOLLECTION, GEOMETRYCOLLECTIONM, GEOMETRYCOLLECTIONZ, GEOMETRYCOLLECTIONZM LINESTRING, LINESTRINGM, LINESTRINGZ, LINESTRINGZM MULTICURVE MULTILINESTRING, MULTILINESTRINGM, MULTILINESTRINGZ, MULTILINESTRINGZM MULTIPOINT, MULTIPOINTM, MULTIPOINTZ, MULTIPOINTZM MULTIPOLYGON, MULTIPOLYGONM, MULTIPOLYGONZ, MULTIPOLYGONZM POINT, POINTM, POINTZ, POINTZM POLYGON, POLYGONM, POLYGONZ, POLYGONZM POLYLINE, POLYLINEZ RING, RINGM, RINGZ, RINGZM

Some less popular types are not yet supported: CIRCULARSTRINGM, CIRCULARSTRINGZ, CIRCULARSTRINGZM COMPOUNDCURVEM, COMPOUNDCURVEZ, COMPOUNDCURVEZM CURVE, CURVEM, CURVEZ, CURVEZM CURVEPOLYGONM, CURVEPOLYGONZ, CURVEPOLYGONZM GEOMETRY, GEOMETRYZ, GEOMETRYZM MULTICURVEM, MULTICURVEZ, MULTICURVEZM MULTIPATCH MULTISURFACE, MULTISURFACEM, MULTISURFACEZ, MULTISURFACEZM POLYHEDRALSURFACE, POLYHEDRALSURFACEM, POLYHEDRALSURFACEZ, POLYHEDRALSURFACEZM POLYLINEM SURFACE, SURFACEM, SURFACEZ, SURFACEZM TIN, TINM, TINZ, TINZM

For the sake of speed and scalability, spatial support has some intentional restrictions, that will probably persist for long time.

--- No support for circumpolar shapes. A ring with a pole inside it or on the border of it may be treated as an error or result in wrong calculations of spatial relations. E.g. the st_intersects of two triangles POLYGON((0 89, 120 89, 240 89, 0 89)) and POLYGON((0 88, 120 88, 240 88, 0 88)) may return FALSE. st_intersects of two triangles POLYGON((0 89, 60 90, 120 89, 0 89)) and POLYGON((120 88, 180 90, 240 88, 120 88)) may also return FALSE. Note that Equator is a circumpolar shape.

--- No support for long orthodromic or near-orthodromic arcs. The implementation assumes that shapes reside inside their bounding boxes so st_intersects of two orthodromic arcs, LINE (0 1, 180 1) and LINE (90 1, 270 1) may return FALSE. However big shapes made of small segments (such as a coastline of Eurasia) will be handled correctly. Shapes that are close to 180 longitude get two sets of bounding boxes, shifted 360 one from another, so relations between Alaska and Chukotka will be calculated correctly no matter what offset is used.

--- In order to deal with weird data sources, the range for longitudes is -270 to -540 and the range for latitudes is -90 to +90 for most cases and -96 to +96 for some features such as bounding boxes. If the parsing of a shape did not report range errors for co-ordinates then there's no warranty that all points are in WGS ranges.

--- Peculiarities like self-touch or self-intersection of polygons can be detected, but no warranties are given.

--- Arcstrings are poorly supported and their support will never be optimized for speed. Each arc is supposed to be no longer than 180 degrees. As a result, ESRI circles that consist of two arcs 180+180 are supported whereas ST_Intersects on "ill" circles like 270+90 may return wrong answers.

9.34.3. Precision of Geometries

The internal precision of geometry operations is 64 bit IEEE floating point. Normally, a geometry index for geography uses can be made with 32 bit floats for space efficiency, as these still give a precision of about 2 meters on the surface of the Earth. A geometry object is stored with all coordinates either as float or double depending on which data type was supplied in creating the object. Note that the object itself can have more precise coordinates than the representation of its bounding box in the R tree index.

Bounding boxes for shapes can be calculated approximately as soon as shape contain any arcs. In any case, bounding box of a shape is a bit bigger than the shape itself in order to tolerate rounding errors. Predicates for spatial relations accept an additional, non-standard, argument for tolerance. If the tolerance is greater than zero, borders of shapes are treated as wide lines with thickness is approximately equal to the specified tolerance. That is useful for dealing with inaccurate data such as amateur GPS/GLONASS tracks, coordinates rounded to minutes when published in Dbpedia and the like.

9.34.4. Predicates

```
isgeometry (in x any)
```

Returns 1 if the argument is a geometry.

See Also:

`isgeometry`

9.34.5. Querying Geometric Relations

The SQL MM predicates `st_intersects` , `st_contains` and `st_within` can be used to test whether two geometries overlap in different ways.

`st_intersects` means that the 1st and 2nd arguments have at least one shared point, `st_contains` means that the 2nd argument is fully contained in the 1st argument, `st_within` means that the 1st argument is fully contained within the 2nd argument.

These functions are extended with a third argument which gives a precision. The precision is a number that specifies a maximum distance between two points such that the points will still be considered to overlap. If both the 1st and 2nd arguments are points, then precision can be interpreted as the maximum distance between them.

These do not require the presence of a geometry index but will use one if one is present and one of the geometry arguments is a column on which there is such an index.

9.34.6. Defining a Geometry Index

The below sequence defines a table called geo and a geometry index on its geo column.

```
create table GEO (ID bigint, GEO any, primary key (ID))
 alter index geo on geo partition (id int);

CREATE TABLE GEO_INX ( X real no compress,
                       Y real no compress,
                       X2 real no compress,
                       Y2 real no compress,
                       id bigint no compress,
                       primary key (X, Y, X2, Y2, id))
                       ALTER INDEX geo_inx ON geo_inx PARTITION (id int);

INSERT INTO sys_vt_index ( vi_table,
                           vi_index,
                           vi_col,
                           vi_id_col,
                           vi_index_table,
                           vi_id_is_pk,
                           vi_options)
  VALUES ('DB.DBA.GEO',
          'GEO',
          'GEO',
          'ID',
          'DB.DBA.GEO_INX',
          1,
          'G');

-- Reload the changed schema
__ddl_changed ('DB.DBA.GEO');
```

A geometry index is a table of always five columns, the first 4 are the lower x, y and higher x, y of the object's bounding box, id is the identifier of the object, a foreign key into the table holding the geometries. In a cluster setting the geometry index must be partitioned on the id column. The columns of a geometry index must never be compressed, hence the mandatory no compress declaration.

Geometry indices are declared in the sys_vt_index table, which also declares text indices. The G in the options column declares that this is a geometry index.

A geometry index will be used when appropriate. The table holding the R tree with the bounding boxes should not normally be accessed directly. Explicit selects from a geometry index table with conditions on the columns will not generally work since the collation is not linear as in a regular index. Inserts by means other than geo_insert are not allowed.

9.34.7. Insert and Delete

```
geo_insert (in tb any, in geo any, in id int);
geo_delete (in tb any, in geo any, in id int);
```

These functions insert and delete a geometry from an R tree index. The tb must be a fully qualified name of an R tree table.

These functions will typically be used from triggers on a geometry column. The functions are transactional and make a transaction log record of the action.

See Also:

`geo_insert`

`geo_delete`

9.34.8. Using Geometries in Client Applications and SQL Procedures

In SQL procedures, a geometry is a member of the ANY data type. The `isgeometry ()` function can be used for testing if an object is a geometry. A geometry can only be stored in a column declared to be of type ANY.

If a geometry would be returned to a client application as part of a result set, it is returned as a string containing its WKT text representation. For a client application to pass geometries to the server, it must pass these either as a WKT string parameter to st_geomfromtext or as numeric coordinate values for st_point or related functions. This applies to all clients, ODBC, JDBC, .net and any RDF frameworks.

See Also:

RDF and Geometry

9.34.9. Virtuoso 7.1+ Geo Spatial Data type and function enhancements

As of Virtuoso 7.1+ (open source and commercial) a number of major enhancements in Geo Spatial support have been made to improve the Geometry data types and functions supported, as well as improve compliance with the emerging GeoSPARQL and OGC standards.

Virtuoso Geo Spatial Geometry data types and sample queries

The table below outlines the common WKT (Well Known Text) representations for several types of geometric objects used in RDF:

Figure 9.1. Geo Spatial Geometry Data Types

Geometry Type	WKT representation
Point 	POINT(3 7)
Multipoint 	MULTIPOINT(3 7, 4 2, 8 6)
LineString 	LINESTRING(1 2, 3 6, 9 4)
MultiLineString 	MULTILINESTRING((1 8, 4 4), (4 9, 8 5, 6 2, 1 4))
Polygon 	POLYGON((1 2, 6 1, 9 3, 8 5, 3 6, 1 2))
Polygon (*with hole*) 	POLYGON((1 2, 6 1, 9 3, 8 5, 3 6, 1 2), (3 3, 5 5, 6 2, 3 3))
MultiPolygon 	MULTIPOLYGON(((1 2, 6 1, 9 3, 3 6, 1 2)), ((4 9, 7 6, 9 8, 4 9)))
GeometryCollection 	GEOMETRYCOLLECTION(POINT(4 5), POINT(7 4), POINT(6 2), LINESTRING(4 5, 6 7, 7 4, 6 2), POLYGON((1 2, 6 1, 9 3, 8 5, 3 6, 1 2)))

The following queries "counts the number of items of each type whose coordinates fall within a bounded box shape" for the various RDF geometry data types now supported by Virtuoso. The links are to live examples of the query running against the OpenLink LOD Cloud Server instance.

Virtuoso Geo Spatial geometry functions

The following Virtuoso Geo Spatial geometry functions are available for use in both SQL and RDF Geo Spatial queries. The listed functions are built-in SQL functions. As all built-in functions of Virtuoso, geo-specific functions can be called from SPARQL with prefix `bif:` . For example:

```
bif:earth_radius()
etc.
```

- `earth_radius()` : returns geom.mean of radius of Earth in kilometers, 6367.43568
- `haversine_deg_km (lat1, long1, lat2, long2)` : returns distance between two points on Earth sphere, adjusting radius of sphere to latitudes.
- `dist_from_point_to_line_segment (Xpoint, Ypoint, Xsegment1, Ysegment1,Xsegment2, Ysegment2)` : returns the distance between a point and a segment on a plane.
- `st_point` : returns a point with given coordinates in default SRID. z and/or m may be missing or equal to NULL, indicating the absence of co-ordinate.
- `st_linestring (item1, item2,..., itemN)` : returns a linestring in default SRID, the coordinates of vertices are specified by arguments that are points, 2-, 3- or 4-item vectors of coordinates, linestrings, arcstrings or vectors of the above mentioned values. Repeating vertices are automatically removed, except the case of repeating vertices in the middle of a linestring/arcstring argument.
- `st_x()` : returns X or longitude of a point.
- `st_y()` : returns X or longitude of a point.
- `ST_XMin (shape)` ,

  `ST_YMin (shape)` ,

  `ST_XMax (shape)` ,

  `ST_YMax (shape)` : return boundaries of a bounding box around a shape. Bounding boxes around arcs are calculated in assumption that no one arc is longer than a half of full circle.
- `st_intersects (shape1, shape2 [, proximity])` : checks whether two shapes intersect or some of its points are within the specified proximity. Current version is not complete and does not support arcs of all sorts and rings of polygons, this is fixed in the next release.
- `st_may_intersect (shape1, shape2 [, proximity])` : checks whether bounding boxes of two shapes intersect or some of its points are within the specified proximity. This is much faster than full

  `st_intersects()` check (actually that is the initial part of

  `st_intersects()` execution)
- `(haystack_shape, needle_shape [, proximity])` :

- `st_within (needle_shape, haystack_shape [, proximity])` : checks whether `haystack_shape` contains the `needle_shape` . If proximity is specified, it is treated as an extra wide border around `haystack_shape` . In current version, only a combination of bounding box and a point is supported, the functionality will be extended in the next release.
- `st_distance (shape1, shape2)` : returns the distance in units of plane or in kilometers on sphere.
- `isgeometry (v)` : returns whether the given v is a spatial object.
- `st_astext (shape)` : returns EWKT representation of a shape.
- `ST_SRID (shape)` : returns SRID of shape's spatial reference system or 0 for shape on plane.
- `ST_SetSRID (shape, new_srid)` : replaces the SRID of a shape but does not transform the shape or its coordinates from old SRID to a new one.
- `st_geomfromtext (ewkt_text)` : Parses the string and returns the corresponding geometry.
- `st_ewkt_read (ewkt_text)` : Parses the giwen text as a EWKT and returns the parsed shape.
- `http_st_ewkt (shape, ses)` : Writes a EWKT representation of a shape to the given session, a fast replacement for

  `st_astext (shape)` .
- `http_st_dxf_entity (shape, attrs, ses)` : writes a DXF (Data Exchange Format) representation of shape into the given output session.Attrs is a vector of arbitrary DXF properties in form (tag1, value1, tag2, value2...) where tags are integer codes according to DXF specification, related values are not validated and printed to the session as is. Current version does not support ARCSTRINGs, CURVEs and CURVEPOLYGONs. If shape is null, the function returns without writing anything to the shape.
- `st_get_bounding_box (shape)` : returns BOX2D that is a bounding box of a shape.
- `GeometryType (shape)` : returns EWKT type name of a shape.
- `ST_NumGeometries (shape)` : returns number of members of a MULTI... or ...COLLECTION shape, 1 for other sorts of shapes.
- `ST_GeometryN (shape, idx)` : Given a 1-based index of a member of a MULTI... or ...COLLECTION shape, returns the member.
- `ST_ExteriorRing (polygon_shape)` : Returns an external (the very first) ring of a polygon.
- `ST_NumInteriorRings (polygon_shape)` : returns number of interior rings of the given polygon, NULL if shape is not a polygon.
- `ST_InteriorRingN (polygon_shape, idx)` : Given a 1-based index of an interior ring of a polygon, returns the ring. Wrong index is not reported as an error and NULL is returned.
- `st_get_bounding_box_n (shape, idx)` : Given a 1-based index of a member of a MULTI... or ...COLLECTION shape, returns the bounding box of a member. This is a fast equivalent of

  `st_get_bounding_box (ST_GeometryN (shape,idx))` .
- `ST_Translate (shape, dX, dY [, dZ])` : returns a copy of a shape with all coordinates shifted by the provided dX, dY and dZ.
- `ST_TransScale (shape, dX, dY, Xfactor, Yfactor)` : returns a copy of a shape with all coordinates shifted by the provided dX, dY and then multiplied by Xfactor and Yfactor. In current version, differente values for Xfactor and Yfactor will result in distorted arcs.
- `st_transform_by_custom_projection (shape, algorithm_id, ...)` : Performs a custom projection of shape, using the specified algorithm and algorithm-specific arguments. Current version supports only one algorithm, `st_transform_by_custom_projection (shape, 'OLAEAPS', long_of_center, lat_of_center)` for Oblique Lampert Azimuthal Equal-Area Projection System with the specified center point.
- `ST_Transform (shape, deST_SRID, [orig_proj4_string, dest_proj4_string])` : Transforms the given shape from its current spatial reference system to one specified by `deST_SRID` . Two optional arguments are for "cheating": the SRID of the resulting shape is set to `deST_SRID` but the conversion is done by proj4 using `origin_proj4_string` for projection of original shape and `dest_proj4_string` for the result. If `orig_proj4_string` or `dest_proj4_string` argument is passed but is NULL instead of string, the projection corresponding to original or destination SRID is used. `ST_Transform` is provided by a separate plugin named v7proj4, as described below. When the plugin is loaded, functions like `st_intersects()` support pairs of arguments with different SRIDs by converting coords of second argument into the system of the first one, as required by OGC and GeoSPARQL.
- `postgis_proj_version()` : Returns the version of proj4 in use, as a string, for compatibility with PostGIS.

v7proj4 plugin

The Virtuoso v7proj4 hosted plugin module is required for performing transformation between different co-ordinates systems using the `ST_Transform()` function. The plugin is based on Frank Warmerdam's proj4 library and it's practical to have the proj4 package installed on every box of Virtuoso cluster, even if the build is performed on single machine or on different location

at all. The reason is that the plugin should load data about coordinate systems to work and the simplest way to get the right data from a high-quality source is to use the package.

Compiling open source v7proj4 plugin

The v7proj4 is currently available in the default develop/7 branch of the "v7fasttrack " git repository and can be build as follows:

```
git clone https://github.com/v7fasttrack/virtuoso-opensource.git
cd virtuoso-opensource
./autogen.sh
export CFLAGS="-msse4.2 -DSSE42"
./configure
make -j 24
make install
```

Note first the "proj.4" library must be installed on the system and can be proj.4 download area, which the configure script will detect the installation of enabling the v7proj4 plugin library to be built in ~/libsrc/plugin/.libs:

```
ls libsrc/plugin/.libs/v7proj4*
libsrc/plugin/.libs/v7proj4.a
libsrc/plugin/.libs/v7proj4.la
libsrc/plugin/.libs/v7proj4.lai
libsrc/plugin/.libs/v7proj4_la-import_gate_virtuoso.o
libsrc/plugin/.libs/v7proj4_la-sql_v7proj4.o
libsrc/plugin/.libs/v7proj4_la-v7proj4_plugin.o
libsrc/plugin/.libs/v7proj4.so
libsrc/plugin/.libs/v7proj4.ver
```

Installation and Configuration of v7proj4 plugin

When the plugin (v7proj4.so) is built, it needs to be added to the [Plugins] section of Virtuoso configuration file (virtuoso.ini or the like), also on every node of a cluster:

```
[Plugins]
LoadPath = ./plugins
Load2    = plain, v7proj4
```

If everything is fine then the virtuoso.log file will contain something like the following lines after the next startup:

```
21:30:10 { Loading plugin 1: Type `plain', file `shapefileio' in `.'
21:30:10   ShapefileIO version 0.1virt71 from OpenLink Software
21:30:10   Shapefile support based on Frank Warmerdam's Shapelib
21:30:10   SUCCESS plugin 1: loaded from ./plugins/shapefileio.so }
21:30:10 { Loading plugin 2: Type `plain', file `v7proj4' in `.'
21:30:11   plain version 3208 from OpenLink Software
21:30:11   Cartographic Projections support based on Frank Warmerdam's
proj4 library
21:30:11   SUCCESS plugin 2: loaded from ./plugins/v7proj4.so }
21:30:11 OpenLink Virtuoso Universal Server
21:30:11 Version 07.10.3208-pthreads for Linux as of Mar 31 2014
...
21:30:28 PL LOG: Initial setup of DB.DBA.SYS_V7PROJ4_SRIDS data from
files in "/usr/share/proj"
21:30:30 PL LOG: DB.DBA.SYS_V7PROJ4_SRIDS now contains 6930 spatial
reference systems
...
21:30:32 Server online at 1720 (pid 9654)
```

To store descriptions of coordinate systems, the plugin creates a table:

```
create table DB.DBA.SYS_V7PROJ4_SRIDS (
 SR_ID integer,
 SR_FAMILY varchar not null,
 SR_TAG varchar,
 SR_ORIGIN varchar not null,
 SR_IRI IRI_ID_8,
 SR_PROJ4_STRING varchar not null,
 SR_WKT varchar,
 SR_COMMENT varchar,
```

```
 SR_PROJ4_XML any,
 primary key (SR_ID, SR_FAMILY) )
;
```

and fills it with data from files epsg, esri, esri.extra, nad83 and nad27 of directory /usr/share/proj. Note these files must exist in the /usr/share/proj directory otherwise a message will be reported in the log file indicated the file could not be found. Every row of the table is identified with name of "family" of coordinate systems and an integer SRID. Different sources may assign same SRID to different reference systems, however descriptions of well-known systems match exactly or the difference is not noticeable for any practical application.

The loading process uses family names 'EPSG', 'ESRI', 'NAD83' and 'NAD27'. When the `ST_Transform()` searches for a coordinate system that corresponds to a given SRID then it returns first record found while checking the following families in the following order: 'PG', 'EPSG', 'ESRI','NAD83', 'NAD27'. Thus it is practical to put all custom definitions in 'PG' family, thus they will get the highest priority.

A sample EPSG file containing the mapping for the proj.4 EPSG:4326 coordinate system is:

```
$ cat /usr/share/proj/epsg
<4326>+proj=longlat +ellps=WGS84 +datum=WGS84 +no_defs<>

SQL> SELECT * FROM DB.DBA.SYS_V7PROJ4_SRIDS;
SR_ID             SR_FAMILY          SR_TAG    SR_ORIGIN              SR_IRI    SR_PROJ4_STRING
INTEGER NOT NULL  VARCHAR NOT NULL   VARCHAR   VARCHAR NOT NULL       VARCHAR   VARCHAR NOT NULL
_____________________________________________________________________________________________

4326              EPSG               4326      /usr/share/proj/epsg   NULL      +datum=WGS84 +ellps=WGS84

1 Rows. -- 0 msec.
SQL>
```

There are two procedures are available for loading more co-ordinate systems:

1. `DB.DBA.V7PROJ4_LOAD_SYS_SRIDS` : it is called at server startup if the v7proj4 plugin is loaded:

   ```
   DB.DBA.V7PROJ4_LOAD_SYS_SRIDS (
     in projdir varchar := '/usr/share/proj',
     in only_if_empty_table integer := 0
   )
   ```
2. `DB.DBA.V7PROJ4_LOAD_INIT_FILE` : it is lower-level procedure:

   ```
   DB.DBA.V7PROJ4_LOAD_INIT_FILE (
     in path varchar,
     in _sr_family varchar
   )
   ```

The main part of `DB.DBA.V7PROJ4_LOAD_SYS_SRIDS()` is a sequence of:

```
DB.DBA.V7PROJ4_LOAD_INIT_FILE (projdir || '/epsg', 'EPSG');
DB.DBA.V7PROJ4_LOAD_INIT_FILE (projdir || '/esri', 'ESRI');
DB.DBA.V7PROJ4_LOAD_INIT_FILE (projdir || '/esri.extra', 'ESRI');
DB.DBA.V7PROJ4_LOAD_INIT_FILE (projdir || '/nad83', 'NAD83');
DB.DBA.V7PROJ4_LOAD_INIT_FILE (projdir || '/nad27', 'NAD27');
```

Rows with same SRID but different `SR_FAMILY` may exist in the table, however only one projection per SRID is used and `SR_FAMILY` defines the priority. The internal search query for projection by SRID is:

```
SELECT COALESCE
   (
     ( SELECT SR_PROJ4_STRING FROM DB.DBA.SYS_V7PROJ4_SRIDS WHERE SR_ID=:0 AND SR_FAMILY='PG'),
     ( SELECT SR_PROJ4_STRING FROM DB.DBA.SYS_V7PROJ4_SRIDS WHERE SR_ID=:0 AND SR_FAMILY='EPSG'),
     ( SELECT SR_PROJ4_STRING FROM DB.DBA.SYS_V7PROJ4_SRIDS WHERE SR_ID=:0 AND SR_FAMILY='ESRI'),
     ( SELECT SR_PROJ4_STRING FROM DB.DBA.SYS_V7PROJ4_SRIDS WHERE SR_ID=:0 AND SR_FAMILY='NAD83'),
     ( SELECT SR_PROJ4_STRING FROM DB.DBA.SYS_V7PROJ4_SRIDS WHERE SR_ID=:0 AND SR_FAMILY='NAD27')
   )
```

so for `ST_Transform()` function 'PG' overrides everything else, EPSG is the next highest priority, then ESRI, NAD83 and NAD27. However custom queries and procedure may select whatever they please, including sr families not listed here or strings

from other tables etc., and feed projection strings directly to `ST_Transform()` .

The co-ordinate systems can also be updated by direct manipulations on `DB.DBA.SYS_V7PROJ4_SRIDS table` (the table it is readable for public and writable for DBA only). When the table is edited, call function "`Proj4 cache_reset()` " to prevent SQL runtime from using previously prepared projections that might become obsolete after changes in the table. Note that proj4 projections are for normalized data in radians whereas Virtuoso stores shapes using numbers that come from WKT, i.e. they're latitudes and longitudes in degrees for almost all cases.

The v7proj4 plugin automatically applies `RAD_TO_DEG` multiplier before conversion and/or `RAD_TO_DEG` multiplier after conversion when source and/or destination coordinate systems are latitude-longitude or geocentric. Even if this conversion is done automatically, you should remember that it happens, for the following reason. Many "how-to" instructions for spatial data sets contain paragraphs like "how to convert these data to WGS-84" and sample C/C++ code contains transformations like `{ x *= RAD_TO_DEG; y *= RAD_TO_DEG; }` . These transformations will probably be redundant in the corresponding Virtuoso/PL code whereas proj4 strings can be used unchanged and passed as 3rd and 4th arguments of `ST_Transform()` function. If degrees-to-radians conversion is made twice then the data can be calculated as if the shape is located in a totally different place of ellipsoid. If the post-transformation radians-to-degrees conversion is also made twice, the resulting shape may look like the real one but coordinates may be tens kilometers away from correct values.

ST_Transform() Example

Below are some example uses of the `ST_Transform()` function to transform some of the sample coordinate systems load into Virtuoso:

```
SQL> SELECT * FROM DB.DBA.SYS_V7PROJ4_SRIDS;
SR_ID               SR_FAMILY           SR_TAG    SR_ORIGIN               SR_IRI    SR_PROJ4_STRING
INTEGER NOT NULL    VARCHAR NOT NULL    VARCHAR   VARCHAR NOT NULL        VARCHAR   VARCHAR NOT NULL
_____________________________________________________________________________________________

2005                EPSG                2005      /usr/share/proj/epsg    NULL      +ellps=clrk80 +k=0.99950
2249                EPSG                2249      /usr/share/proj/epsg    NULL      +datum=NAD83 +ellps=GRS8
4326                EPSG                4326      /usr/share/proj/epsg    NULL      +datum=WGS84 +ellps=WGS8

3 Rows. -- 1 msec.
SQL> SELECT ST_Transform (st_geomfromtext ('POLYGON((-16 20.25,-16.1 20.35,-15.9 20.35,-16 20.25))'), 1,

9.35. SQL Bulk Load, ELT, File Tables and Zero Load Operations

9.35.1. File Tables

Virtuoso supports mapping files of comma separated values as tables from version 7.00.3206. This makes bulk load of relational data straightforward and very fast. This also makes it possible to query data in files without any loading into the database. The latter is specially convenient if data is queried just once, where loading and subsequently dropping the data would be needless overhead. Also arbitrary ETL transformations can be expressed in SQL, reading from a file table and inserting into a database table. This includes the whole range of SQL functionality, including intermediate aggregations and the like.

This feature deprecates the CSV load functions in previous versions, e.g. csv_load.

Queries can freely mix file tables and regular tables. Joins with file tables make hash join plans where the smaller file is copied into a memory resident hash table. For very large hash tables, partitioned hash join can be used, thus arbitrary joining between

files is possible, fast and convenient.

A file table is declared with a regular create table statement. If the table definition includes a primary key, the file is assumed to be sorted as declared. In most cases a primary key should not be declared when creating a file table. After the create table statement, the procedure fs_set_file declares that the table is in fact a file. In a cluster setting the file should be visible to all the server processes via a shared file system.

For example, to bulk load the TPC-H part table:

```
CREATE TABLE PART_F (
    P_PARTKEY     INTEGER NOT NULL,
    P_NAME        VARCHAR(55) NOT NULL,
    P_MFGR        CHAR(25) NOT NULL,
    P_BRAND       CHAR(10) NOT NULL,
    P_TYPE        VARCHAR(25) NOT NULL,
    P_SIZE        INTEGER NOT NULL,
    P_CONTAINER   CHAR(10) NOT NULL,
    P_RETAILPRICE double precision NOT NULL,
    P_COMMENT     VARCHAR(23) NOT NULL    );

ft_set_file ('PART_F', 'src/part.tbl', delimiter => '|');

-- turn off logging and set insert mode to auto committing, non-transactional
log_enable (2);

-- read the file and insert into the previously create part table
insert into part select * from part_f;
```

The ft_set_file procedure takes the table name as first argument and a file system path relative to the server's working directory as the second argument. Optional arguments allow specifying a delimiter, newline character and escape character.

```
create procedure ft_set_file (in tb varchar, in fname varchar, in delimiter varchar, in newline v
```

Creating a file table requires dba group privileges and the file is subject to the file system access limitations that apply to file_to_string and other file system access functions.

The newline and escape characters need to be single character strings. A newline or escape character following the escape character is added to the parsed input without its special interpretation.

Each column in the CSV file is expected to end with the delimiter character. A field of zero length is considered a SQL NULL value, i.e. if two delimiters are adjacent or if a line begins with the delimiter, the field is considered NULL. The text in the field is parsed according to the data type declared for the column whose position in the create table corresponds to the field position on the line. The parsing is as by the SQL cast function from a varchar value. If the cast fails the line is silently ignored.

When a table is declared as a file table, the file is sampled and statistics are written into the sys_col_stat table. In this way the system is capable of making correct query plans involving joins of file tables. For this reason, the file should exist and have the relevant content when the file table is created.

A file table will be read in parallel on multiple threads if a normal table would be read in parallel in the same situation. In a single server, the ThreadsPerQuery (enable_qp in sys_stat) setting controls the number of threads used. In a cluster setting each elastic slice corresponds to a fraction of the file. This is why the file is expected to be visible from all the servers.

If a table had previous content and subsequently was declared a file table, the previous content will no longer be visible. The file table may cease to be a file table by the dba deleting the corresponding row from sys_file_table and calling __ddl_changed on the file table. At this point the previous, databases resident content of the table will be visible again. However the statistics gathered from the file will still shadow the statistics of the table.

It is often the case that many CSV files have the same structure. For these cases it is sufficient to create a single table and attach it to one of the files with ft_set_file. This file will provide the statistics. In order to read a different file, one can use the FROM clause in the TABLE OPTION clause of in the FROM clause of a select statement, as follows:

```
-- get the count of well formed part rows from the part.tbl file
SELECT COUNT (*)
  FROM part_f;
```

```
-- do the same from src/part.tbl.2
SELECT COUNT (*)
  FROM part_f TABLE OPTION (FROM 'src/part.tbl.2');
```

The value of the FROM option can be an arbitrary expression, however it must be independent of values bound by the containing statement. It may depend on variables bound in an enclosing stored procedure or from parameters but it cannot join to a column of another table in the same select statement.

Arbitrary search conditions can be applied to file tables, for example:

```
SELECT p_name, p_size, p_partkey
  FROM part_f
 WHERE p_name LIKE '%green%';
```

Joins are possible, for example:

```
SELECT SUM (ps_availqty)
  FROM partsupp, part_f
 WHERE ps_partkey = p_partkey
   AND p_name LIKE '%green%';
```

This would join the partsupp table to the part file.

File tables are not cached by the DBMS, they are read from the OS every time they are needed. A single query will not read the same file multiple times, unless in the case of a partitioned (multtipass) hash join. Nested loop joins are not applied to file tables. File tables cannot be updated and no transaction control applies to them. Select permissions can be granted as for any other table.

9.35.2. Parallel Insert With File Tables and Transactions

A file table is copied into a database resident table with an INSERT... SELECT statement. Such a statement executes in parallel if the session is in auto commit mode, i.e. log_enable (2) or log_enable (3) has been previously executed on the session.

A file can be loaded inside a transaction if the connection is not in auto commit log_enable (2) or 3. This will be multithreaded if enable_mt_txn is 1 in the [Flags] section of the ini file or __dbf_set ('enable_mt_txn', 1) has been executed previously. The setting is global. Defaults vary according to server version. Use sys_stat ('enable_nt_txn') to read the value of the setting.

For long files the transaction is liable to run out of rollback space. File table operations as such do not affect the transaction context. Explicit commits may be interspersed in a select statement from a file or other tables.

For example, the history keeping dimension updates from TPC DS can be implemented as follows. The item table is a history keeping dimension that has an index on the i_item_id business key and has a primary key of item surrogate key, with a new value for each version of the item record. The item record has a start and end date (i_rec_start_date, i_rec_end_date) to mark the period of validity of the information. A null value in item_rec_end_date marks the currently applicable record. When the item data is updated, the, a new item is inserted and the previously current item record has its end date set to the current date. These operations must occur atomically. Otherwise the implementation may choose whether to update many item records in the same transaction.

In the below listing most columns have been left out for brevity:

```
CREATE PROCEDURE item_update (in i_id varchar,...)
{
  vectored;

  UPDATE item
     SET i_rec_end_date = curdate
   WHERE i_id = i_id
     AND i_rec_end_date IS NULL;

  INSERT INTO item (i_ietm_sk, i_item_id, i_rec_end_date,...)
           VALUES (sequence_next ('item_sk_seq'), i_id, NULL,... )
  not vectored { COMMIT WORK};
}

SELECT COUNT (item_update (i_item_id,....)
  FROM item_f....;
```

The select statement call the item_update procedure on a vector of item ids and other columns. The procedure marks the expired record and inserts the new record, assigning new surrogate keys from a sequence. After each batch it performs one commit. The next batch of items are updated in a separate transaction.

This should be run on a single thread. In a multithreaded transaction the threads may not issue individual commits. The code could be multithreaded by leaving out the commit from the stored procedure. Then the commit would have to be after the completion of the select statement.

The following isql script bulk loads a whole TPC-H database. We leave out the create tables and ft_set_files for brevity, they are all as in the part example above.

```
log_enable (2); INSERT INTO lineitem SELECT * FROM lineitem_f &
log_enable (2); INSERT INTO orders   SELECT * FROM orders_f &
log_enable (2); INSERT INTO customer SELECT * FROM customer_f &
log_enable (2); INSERT INTO part     SELECT * FROM part_f &
log_enable (2); INSERT INTO partsupp SELECT * FROM partsupp_f &
log_enable (2); INSERT INTO supplier SELECT * FROM supplier_f &
log_enable (2); INSERT INTO nation   SELECT * FROM nation_f &
log_enable (2); INSERT INTO region   SELECT * FROM region_f &

wait_for_children;
checkpoint;
```

A multithreaded, non-logged, non-transactional insert is started for each table-file pair as a background task. The wait_for_children isql command waits for all the background tasks to complete. The checkpoint statement makes the state durable. Killing the server in before the checkpoint would result in the server starting in a state with none of the effects of the bulk load present, since the log_enable(2) turns off logging. The database is online during the bulk load and the progress may be followed by periodically counting the tables, for example.

Chapter 10. Virtuoso Cluster Programming

Abstract

This chapter contains cluster programming aspects such as explaining the basics of how SQL queries work on clustered Virtuoso, sql options, Sequences and identity columns, Distributed Pipe constructions and many others. It also describes RDF tables partitioning and troubleshooting.

These sections apply to Virtuoso as of version 6.0.

10.1. Cluster SQL Execution Model

This section explains the basics of how SQL queries work on clustered Virtuoso.

Query optimization for cluster is similar to query optimization for a single process. The main issues of optimization have too do with join order, index choice and join type.

Still, the performance characteristics of a distributed memory cluster are radically different from a single process database. Namely, the cost of a network round trip between nodes, even if these were only different processes on a shared memory multiprocessor, is between 5 and 50 single row lookups from a big table, supposing the row being sought for is in memory. The 5x factor applies when within the same machine, the 50 times factor applies over 1Gbit ethernet.

From this follows that a single network message must process several hundred rows and several messages must be concurrently dispatched to multiple nodes for clustering to yield any benefit in terms of a single query's processing time.

Of course, a cluster can have essentially unlimited RAM, which is not the case of a single machine and a network round trip remains faster than a disk random access. For serial throughput, the disk controller is several times faster than the network, though. Of course, with large numbers of concurrent users, the latencies get absorbed and a high aggregate throughput can be attained.

Still, the first question of any distributed memory system is the aggregation of messages. This can be done in two complementary ways: By Sending a large number of simple operations in a single message, preferably asynchronously to multiple recipients and on the other hand by putting more complex operations into a message.

Also, a random access pattern can be transformed to a serial access pattern by using hash join, i.e. making a temporary copy of an index or part thereof. In this way, the query does not have to go to the data more than once even if it is used inside a tight loop in the query plan.

We will use the TPC H tables to illustrate some points below:

When performing a loop join, Virtuoso will run as many iterations as possible in parallel. Consider a join like:

```
select o_date
  from nation, customer, order
 where o_custkey = c.custkey
   and c_nationkey = n_nationkey
   and n_name = 'FRANCE';
```

We presume the indices:

```
create index c_nk on customer (c_nationkey) partition (c_nationkey int)
create index o_ck on orders (o_custkey) partition (c_custkey int);
```

This gets the order dates for order by customers in France. This is typically a loop join since this is expected to access a fraction of orders at random. First we get the n_nationkey for France. Then we get the c_custkey for French customers. This is a sequential read of an index and produces a set of c_custkey values. Given these, we join to orders using the o_ck index. This index produces a set of o_orderkey values for each o_custkey. These are then used for getting the o_date's from the actual order row.

If the batches are large enough, the query will execute in 3 network round trips: One to get the set of c_curstkey's for France, one to get the o_orderkey's from the o_custkey's and one for getting the o_date for the o_orderkey's. The nation table for getting the n_nationkey for the country name is small and can be replicated on all nodes so this does not count as a round trip.

The first round trip goes to one partition. The resulting c_custkey's will be likely spread over all partitions, so each applicable node gets a message with multiple lookups of the o_ck inde, each with a different o_custkey value. The replies are collated and this time partitioned by o_orderkey and sent as parallel batches to the nodes that hold the actual order rows.

The batch size is settable but is anyway over 1000 operations. The total CPU time for running the query is slightly longer than running the query serially in a single process but the real time is likely shorter because the load is concurrently carried by multiple processes.

Now, if we just wanted the date of the most recent order from France, we could write:

```
select max (o_date)
  from nation, customer, order
 where o_custkey = c.custkey
   and c_nationkey = n_nationkey
   and n_name = 'FRANCE';
```

This would evaluate as explained above but would not return the dates but rather just remember the latest one on each node. At the end, just the latest dates from each cluster node accessed in the query would be returned to the node running the query. Further, SQL specifies that running the same query on the same data is expected to return the same order of results on consecutive runs, even if no order by is present. This means that indices must be traversed in order, i.e. the data received from multiple partitions in indefinite order must be deterministically assembled to provide a predictable order. This is important if slicing the result set for example. When returning an aggregate this condition is relaxed and data can be processed in whatever order received, thus increasing parallelism.

Another optimization is taking advantage of co-located indices.

```
select sum (l_extendedprice)
  from lineitem, orders, customer
 where l_orderkey = o_orderkey
   and o_custkey = c_custkey
   and c_comment like '%fluffily%';
```

This time we scan customers linearly, lookinf for 'fluffily' in the comment field. Finding one, we look for the orders. But we are already in the partition of the c_custkey and the o_ck index of orders is partitioned on this same value, thus we know that the o_orderkey is in fact in the same partition, so no round trip is needed. Then we just send the o_orderkey to the appropriate partition for l_orderkey to get the sum of the extended prices of lines for this customer. At the end of the query, all nodes hosting lineitems will have their local sum and these are just added up and returned.

As long as queries are written as joins, they will run with good parallelism. If they are written as procedure loops and single row lookups from partitioned tables, performance will be an order of magnitude worse.

The join type and join order switches work identically with cluster and single process databases.

10.2. Sequences, Identity and Registry

Sequences and identity columns have a cluster-wide scope. Thus, an identity column can be used as a primary key and partitioning column and the system guarantees that there will be no duplicates.

Sequence numbers are signed 64 bit integers.

The sequence numbers are locally ascending on each node. When a cluster node first requests a sequence number, it is assigned a block of numbers from which it will assign subsequent numbers. Thus, two nodes will allocate from different ranges. The global order is not necessarily ascending but numbers stay unique.

The master node of the cluster keeps a master sequence for each sequence. This is used for allocating blocks of values. The so called:

```
__NEXT__<seq>
```

The sequence itself holds the local next value. The

```
__MAX__<seq>
```

sequence holds the end of the value range allocated for <seq> at the local node.

Allocating a batch of sequence numbers is synchronously logged on both the master node and the requesting node. Thus, upon roll forward recovery, this information survives even if the transaction requesting the numbers was never committed.

The sequence_next function has an additional optional argument for specifying how many values should be requested from the master node at a time.

```
sequence_next (sequence_name[, increment[, batch]])
```

The increment defaults to 1 and the batch to 1000.

Specifying the batch and increment to be equal will get a globally ascending sequence order but will need a round trip to the master for each number.

The registry_get and related functions operate on purely local content. As with single process databases, the registry is used for storing some schema information, sequence values and global application flags.

10.3. SQL Options

For purposes of debugging or writing stored procedures that are specifically meant to work with local data only, it is useful to disable cluster functionality.

This is done with the NO CLUSTER table option. This can be used in the table option clause of a table in a FROM or in an update or delete.

Specially when writing procedures to be called with DAQ, see below, it us necessary to ensure that the procedures will not access data outside of the host running them.

Examples:

```
select count (*) from x table option (no cluster);
update x table option (no cluster) set y = y + 1;
update x set y = 1 where current of cr option (no cluster)
insert into xx key xx option (no cluster) (c1, c2) values (1, 2);
```

Note that for positioned (where current of) deletes and updates the option is at the end. For searched ones it is after the table. Use the explain () function to see the compilation of statements to make sure about the locus of execution. If a table is to be accessed across the cluster, this is indicated in the output.

All other SQL options work as with single server databases.

10.3.1. Parallel INSERT Options

Searched updates and deletes can be parallelized as they are written. However, inserts in loops are not as obviously parallelizable. Therefore insert has an option for queueing multiple inserts into a queue for partitioned parallel execution.

The format of the statement is:

```
INSERT INTO table [KEY <key>] [OPTION (INTO <daq>) <column list> <values or select>
```

The DAQ is a distributed async queue object, see section on calling procedures in cluster. Specifying the INTO daq option partitions the insert, determining where each key should go and buffers the operation into the DAQ. When the result of the DAQ is fetched, all the buffered operations are sent in parallel, as a single message per node concerned. This is easily tens or hundreds of times more efficient than inserting row by row. The transactional behavior is controlled by the DAQ, see the section on calling procedures in cluster. Inserts can mix with other types of operations in the DAQ. If the DAQ is transactional, any failed insert, as in the case of uniqueness violation, will make the transaction uncommittable, preserving integrity.

Example

```
create procedure ct_fill_daq (in n1 int, in n2 int, in st int := 1)
{
 declare daq any;
 declare ct int;
 daq := daq (1);
 for (ct := n1; ct < n2; ct:=ct+st)
 {
 insert into CT option (into daq) (ROW_NO, DT) values (ct, cast (ct as varchar) || ' xxxxxxxxxxxxxx');
 }
 while (daq_next (daq));
}
```

10.3.2. INSERT KEY Option

When indices are partitioned on different columns, indices pertaining to a single row can be located on different nodes. In special situations, for example when exploiting co-location of keys from different tables, one may wish to insert a things index by index. This happens with the use of partitioned functions with DAQ's. Inserting some indices and not inserting others will make an inconsistent database, thus even if keys are inserted separately, all keys should be inserted within the same transaction or have some other guarantee of getting all inserted. Also, application code will have to change if the indices change. This is not considered good practice.

Consider a partition account table and a history table both partitioned on the same key.

We could make a procedure updating the balance of the account and recording the event.

```
create table acct (id int, balance numeric);
alter index acct on acct partition (a_id int);
create table hist (h_id int, ts timestamp, note varchar, primary key (h_id, ts));
alter index hist on hist partition (h_id int);

create procedure evt (in a_id int, in delta numeric, in note varchar)
{
 update acct table option (no cluster) set balance = balance + delta where id = a_id;
 insert into hist key hist option (no cluster) (h_id, note) values (a_id, note);
)
```

Such a procedure would be called on a particular partition using a DAQ In practice, the RDF store uses single key operations for atomically reserving ID's for IRI's, for example..

10.4. Calling Procedures in Cluster

Normally, all interprocess communication in the cluster is transparent. In special cases, the developer may wish to execute a given procedure on a given host of the cluster. This is typically the case when there is affinity between data and logic.

A regular stored procedure or trigger is executed on the host where it is invoked. With the distributed async queue (DAQ) system one can execute procedures on specified remote hosts.

Procedures invoked over DAQ are restricted to dealing with data that is held on the host where they execute. Generic procedures or triggers may use any data from anywhere.

The DAQ offers a mechanism corresponding to the map operation of the map-reduce paradigm. The DAQ may or may not be transactional. In the transactional mode, all the invocations are enlisted into a distributed transaction. The transaction is to be committed separately. The non-transactional DAQ will not enlist operations into a distributed transaction and will automatically

commit after each procedure that executes without error and rollback after each procedure that terminates in an error.

A DAQ is created with the SQL function daq ().

```
daq (in is_txn int) returns any
```

This returns a DAQ object. The object may be passed by value or reference but cannot be returned to a SQL client or passed to another thread or persisted in a table. The DAQ object is a handle for making remote procedure calls and getting their results.

```
daq_call ( in daq any,
           in part_table varchar,
           in part_key varchar,
           in proc varchar,
           in args any,
           in is_update int) returns any
```

This function applies proc to the vectors of args on the host determined by using the partitioning of part_key of part_table designated by args.

Let us suppose that the index part_key of part_table has its 1st and 2nd key part as partitioning keys. Then the 1st element (index 0) of args would be used as the value of the 1st key part and the 2nd element as value of the 2nd key part for determining the relevant partition.

Thus the argument list must be congruent with the layout of the partitioning key. The table or partition key is not referenced otherwise, it is just used for deciding which host gets the call.

If the partition is stored in multiple places, the is_update flag decides whether all will get the call or if only one is picked.

After the host(s) that will get the call are known, the call is queued for execution. The daq_call function returns a vector of two elements. The first is the sequence number of the call. This can be used for associating results to calls. The second element is the list of hosts that got the call.

Each call on each host will produce one or more results. These results are accessed with the daq_next function.

```
daq_next (in daq any) returns any
```

This function returns a result from one of the calls queued on the daq.

The return value can be one of the following:

- 0 - This means that all results have been returned and no more data is available.
- vector with request number, host number and response.

The response is one of:

- Vector with 1 as 0th element - The function returned a result set row. The row is a nested vector as next element.
- Vector with 2 as 0th element. The next element is the return value of the function, the function executed with no error.
- Vector with 3 as 0th element. The next element is a vector describing the SQL error that terminated the function. The error is a nested vector with the constant 3, the SQL state and the text of the message.

If the DAQ is transactional, the first error on the remote host terminates processing. This makes the distributed transaction uncommittable, thus rolling it back at the next transact.

If the DAQ is not transactional, all requests are processed and the state is committed after each function call as a local single phase commit on the processing host. if the function signals an error, the transaction is locally rolled back.

There is no guaranteed order of execution. The calls are buffered until the first call to daq_next. daq_next will return whatever data is first available. If no data from cluster peers is available, it will execute requests that were assigned to the local host. These are executed on the calling thread.

Example

```
create procedure daq_results (in daq any)
```

```
{
 declare row any;
 for (;;)
 {
 row := daq_next (daq);
 if (0 = row)
 return;
 dbg_obj_print (row);
 }
}

create procedure clexec_srv (in str varchar)
{
 exec (str);
}

create procedure clexec (in str varchar)
{
 declare d any;
 d := daq (0);
 daq_call (d, 'DB.DBA.SYS_COLS', 'SYS_COLS_BY_NAME', 'DB.DBA.CLEXEC_SRV', vector (str), 1);
 daq_results (d);
}
```

The clexec procedure will execute the given SQL string on all hosts of the cluster. It returns after all have completed.

10.5. Partition Functions

Given a key and a set of values, the partition function can determine which cluster nodes hold the value.

```
partition_list ( in table_name varchar,
                 in key_name varchar,
                 in list any,
                 in is_update int)
```

The table name is a case sensitive full name of a table as it appears in SYS_KEYS. The key_name is the case sensitive name of the index. The values are key part values in the index order. The is_update, if non-zero, specifies that if the value is stored in multiple places, all are to be returned, otherwise just one is picked at random, preferring the local if there is a local copy of the partition.

The value is a list of node numbers, corresponding to the Host<n> entries in the cluster.ini file.

Example:

```
select partition_list ('DB.DBA.CT', 'CT', vector (2), 1);
```

10.6. Distributed Pipe

A distributed pipe is a single construct that can be used for map-reduce and stream transformation. It is a further development of the DAQ.

A dpipe is an object which accepts a series of input rows and generates an equal amount of output rows. It may or may not preserve order and it may or may not be transactional. The input row of a dpipe is a tuple of values. To each element of the tuple corresponds a transformation. The transformation is expressed as a partitioned SQL function, basically a function callable by daq_call, with arguments specifying the partition where it is to be run. The output row is formed by gathering together the transformation results of each element of the input tuple.

Conceptually, this is like a map operation, like running several DAQ's, one for each column of the dpipe. A transformation function does not always need to produce a value. It may also produce a second partitioned function call with new arguments which will be partitioned and scheduled by the dpipe. Since the second function is independently partitioned, this may be used for implementing a reduce phase. This phase may then return a value and/or further functions to be called.

Ultimately, the dpipe functions are all expected to return a value. When each function of the input row has returned a value, the output row is ready and can be retrieved. Returning a value is a way for the application to synchronize with the operation of the dpipe. The dpipe can be used for mapping values or side effects or both.

The dpipe object is created with the dpipe SQL function. This takes a set of flags and a list of previously declared dpipe transformation names. A dpipe transformation is declared by specifying a SQL procedure, a partitioning key and a set of flags.

The dpipe is fed data with the dpipe_input function. This takes the dpipe object and one value per transformation specified when the dpipe was made. The values can be arrays, so that a transformation function can logically have multiple arguments. The results of the dpipe are retrieved with the dpipe_next function,. This returns a new result row at each subsequent call until one row has been returned for each input row. Depending on flags, these may be returned as they become available or in the original order. Each input is substituted with the transformation result in the output row. Some transformation can be identity so as to preserve a row id for correlating inputs and outputs if they are not processed in order.

After this, the dpipe can be reused. The dpipe is freed when there are no longer references to it.

Finally, since transformations may, in addition to producing values, also produce other functions to be called for their effects, dpipe_reuse is called to make sure that all these functions are run until no more operations are left.

10.6.1. SQL optimization and Dpipe

Calls to SQL functions in queries can be translated to dpipe operations if a dpipe equivalent is declared. Consider a select statement returning the values of a user defined function of some column selected in the query. If this function itself accesses the database, possibly specially if the data accessed is partitioned, calling the function for each row and waiting for the result before processing the next row would have a catastrophic performance impact. The dpipe mechanism allows the functions to be partitioned by the SQL run time and sent to the appropriate cluster nodes as large batches. This applies to any operation that can be expressed as a sequence of steps which will each run within a single partition.

We take a trivial example:

```
create table ct (row_no int primary key, dt varchar);
alter index CT on CT partition (ROW_NO int (255));

create procedure CT_DT_PIPE (in n int)
{
 return vector ((select dt from ct table option (no cluster) where row_no = n), 1);
}

dpipe_define ('CT_DT', 'DB.DBA.CT', 'CT', 'DB.DBA.CT_DT_PIPE', 0);
```

We can now use statements like:

```
select sum (length (ct_dt (row_no))) from ct;
```

This is equivalent to:

```
select sum (length (b.dt))
  from ct a, ct b
  where a.row_no = b.row_no;
```

The point is that the function call will be mapped into the dpipe operation of the same name defined in the dpipe_define. This means that a large batch of row_no's is retrieved and for each, the partition where to invoke the dpipe function is calculated. Then the function calls are sent in concurrent batches to each of these places, running the function in parallel, each on the node that has the data of interest. Getting the value of a column of a partitioned table is a trivial example but any complex computation might be substituted for this, including ones that updated the state on the node, with the proviso that they should not access data from outside the host on which they run.

Further, because the results are summed into an aggregate, the results can be processed in the order they come, thus improving parallelism.

10.7. Cluster and RDF

The RDF tables are partitioned by default on any fresh clustered database. Thus RDF operations are not affected by clustering.

For RDF loading, use the single-threaded load functions DB.DBA.RDF_LOAD_RDFXML and DB.DBA.TTLP. These should essentially always be run in row autocommit mode and without logging. Thus do log_enable (2) on the connection before invoking these functions.

Running these functions in the default transactional mode will load within the current transaction. This will cause widespread locking and will run out of rollback space after some millions of triples. This has a strict transactional semantic but is not generally relevant in RDF applications.

Integrity between all tables and indices is guaranteed after loading the file completes, also in non-transactional mode. After all loading is complete, do a single explicit checkpoint with cl_exec ('checkpoint');

This will guarantee that the disk based image is complete. Automatic checkpoints during non-transactional file loads may have half-files and possibly partial triples in the checkpointed state.

For all SPARUL operations, row autocommit mode is likewise recommended.

Logging is not needed if one makes a manual global checkpoint after any bulk import or update operations. Logging will be useful if one has a continuous feed of smaller files, even if transactional semantics were not needed.

For best import speed, run one or two parallel streams of load commands on each cluster node. Split the data to be loaded into approximately equal chunks and load each with a call to DB.DBA.RDF_LOAD_RDFXML or DB.DBA.TTLP. There is no point in using the _MT variants of these functions on a cluster.

A single load will process about 10000 triples with only about 5 cluster round trips. Still, more of the work is done by the node doing the parsing than by other nodes. To get best use of total throughput, divide the load commands over the cluster nodes. Lock contention will be minimal if the loads are in row autocommit mode. If they are transactional, deadlocks are quite probable due to indeterminate locking order and large transaction size. As a general rule, do not mix transactions and RDF.

10.8. Cluster, Virtual Database and Replication

Clustering has no relation to any virtual database, transactional or snapshot replication mechanism on Virtuoso.

Transactional replication is not supported with clustering. Snapshot replication will work.

Virtual database operations work identically with single process Virtuoso databases. All operations on remote tables are done by the cluster node running the SQL statement. For purposes of symmetry, it is desirable to have all the remote data sources defined for all server processes so that they can be used interchangeably.

An external transaction monitor is not supported with cluster. A Virtuoso cluster could be seen as an XA resource manager but the XA logic is not connected to the cluster transaction logic.

10.9. Troubleshooting

If an operation seems to hang, see the output of status ().

Check for the presence of the following conditions:

- The cluster line shows 0% CPU, no message traffic and an unchanging number of buffers wired, this is probably a bug. To reset, restart the cluster or the offending process if found. Restart is done by executing raw_exit (); over an SQL connection to the process in question.
- The cluster line shows many threads waiting compared to total threads. If CPU is 0 and this does not change there could be a transaction that holds locks indefinitely. To clear, execute txn_killall (1); . Do this at a node that has local threads waiting. This is seen in the Lock Status paragraph of status ('') when connected to the node in question.
- The cluster line shows a changing number in the pfs field. The system is swapping and slowed down.
- If the status () itself hangs, try another process of the cluster. See that there is no temporary atomic activity like a long checkpoint. If the situation persists there is a bug. The checkpoint can be seen by the presence of the checkpinmt_in_progress file in each server's working directory.
- To check the integrity of database files, do cl_exec() ('backup "/dev/null"'); If this returns, the databases are OK. If one is found to be corrupt the corresponding server exits.

Chapter 11. SQL Procedure Language Guide

Abstract

Stored procedures are a key component of database performance. The fewer messages are sent between the client and the server for a given transaction, the faster it will complete.

Virtuoso/PL is a simple and straightforward language for writing stored procedures and triggers in Virtuoso. Its syntax is a combination of SQL and C, making learning it as easy as possible. It offers the features commonly found in database procedure languages in a simple, efficient and concise package. This document presents the primary concepts of the language and ends with a reference section.

11.1. General Principles

A stored procedure is a named piece of Virtuoso/PL code stored in the SYS_PROCEDURES table. Stored procedures are created with the create procedure statement and are used by executing a procedure call statement through the regular SQL API.

A procedure takes zero or more arguments and optionally returns a value. Procedure arguments may be input, output or input and output. In this manner a procedure may modify a variable passed to it by its caller. If the procedure is called from a call statement executed by a client process, the client process gets back the procedure's return value and the values of output parameters.

Procedures can be called with positional or keyword parameters. A call with positional parameters will bind the first argument in the call to the first parameter in the procedure parameter list and so on. A keyword parameter call allows specifying named parameters, where the argument of a given name is bound to the parameter of the same name in the procedure's parameter list. Procedure parameters may be required or optional. The combination of optional parameters and the keyword call notation make it convenient to have procedures with large numbers of parameters of which only part are used at any one time.

Procedures have local variables and cursors that are not visible to other procedures. Procedures can call each other without limitations, including recursively.

In addition to returning a value and changing values of output parameters a procedure may yield one or more result sets. The client can receive rows in result sets just like rows returned by a select statement. A procedure calling another procedure cannot receive a result set produced by the called procedure, however. While parameters and return values work equally well between procedures as between procedure and client application, a result set always goes to the client, even if the procedure has been called by another procedure. A procedure view is a separate construct which allows a procedure to iterate over another procedure's result set. See the Procedure Views section.

A procedure consists of statements and expressions similar to those of any procedural language. In addition, procedures may contain SQL statements operating on the procedure's arguments and local variables. Writing a stored procedure is thus much like using embedded SQL in C, except that a stored procedure is typically much faster.

The elements of the procedure are:

- **Procedure Declaration.** This is a create procedure statement that names the procedure and its arguments.
- **Variable Declaration.** This declares a local variable for the procedure.
- **Cursor Declaration.** This declares a cursor, A cursor allows a procedure to iterate over the rows produced by a select statement.
- **Manipulative SQL statement.** This can be a delete or update statement, either searched or positioned, a cursor manipulation or other so called routine statement.
- **Control statement.** This is any control structure, loop, assignment or procedure call.

- **Handler declaration.** This specifies what to do in a specific exception situation. Exceptions are error conditions produced by SQL statements (e.g. deadlock) or 'not found' situations.

11.2. Scope of Declarations

A declaration can appear anywhere inside a compound statement. It affects all statements in the compound statement following the declaration statement.

11.3. Data Types

Virtuoso/PL supports the regular SQL scalar data types as well as user-defined-types (UDTs). UDTs and structures can be composed of data types or classes made from any hosted language such C# or Java. Local temporary tables are not supported by the present Virtuoso but may be added in the future.

Memory management is automatic. Parameters, cursors and intermediate results are automatically allocated and freed.

A parameter or variable can be of any data type a column can. Variables are however typed at run time, so that the declared type is mostly for documentation. The declared types also affect how interactive SQL shows certain values.

There is a special *vector* construct, declared as type *ANY* , that can be used as an array. Vectors must be instantiated using the `vector()` function, optionally containing initial elements as a comma-separated list, and can be increased in size using the `vector_concat()` . Elements of a vector are read and changed using the `aref()` and `aset()` functions respectively. A special notation can be used as a short-hand for accessing the elements of a vector one-level deep only. The notation is by using the variable with the index in square brackets. Hence, `aref(vec, 1)` is the same as `vec[1]` . The following example reveal more:

Example 11.1. Using Vectors

Simple excerpt showing how to instantiate a vector.

```
declare vec1, vec2, vec3 any;

vec1 := vector();  -- simple empty vector
vec2 := vector('a', 'b', 1, 2);  -- vector of mixed types
vec3 := vector(vector('a', 'b'), vector(1, 2));  -- vector of vectors
```

Second-level elements of vec3 cannot be referenced as vec3[1][1].

Here is the code for a simple VSP page that shows how vectors can be used.

```
<html>
 <body>
<?vsp
declare vec1 any;
declare i integer;

vec1 := vector();

http('loading up the vector using vector_concat...<br>');
i := 0;
while ( i <= 5 ) {
  vec1 := vector_concat(vec1, vector(i * 5));
  i := i + 1;
}

http('displaying the contents using aref<br>');
i := 0;
while ( i <= 5 ) {
  http_value(aref(vec1, i)); http('<br>');
  i := i + 1;
}

http('changing the values using aset<br>');
i := 0;
while ( i <= 5 ) {
```

```
  aset(vec1, i, i * 10);
  i := i + 1;
}

http('displaying the contents using [] notation<br>');
i := 0;
while ( i <= 5 ) {
  http_value(vec1[i]); http('<br>');
  i := i + 1;
}

http('changing the values using [] notation<br>');
i := 0;
while ( i <= 5 ) {
  vec1[i] := i * 15;
  i := i + 1;
}

http('displaying the contents using [] notation again<br>');
i := 0;
while ( i <= 5 ) {
  http_value(vec1[i]); http('<br>');
  i := i + 1;
}
?>
 </body>
</html>
```

Which produces the following output:

```
loading up the vector using vector_concat...
displaying the contents using aref
0
5
10
15
20
25
changing the values using aset
displaying the contents using [] notation

11.4. Handling Result Sets

A single Virtuoso procedure may produce multiple result sets, each with different result columns. A normal procedure produces one empty result set, only returning a possible return value and values of output parameters to the application.

The `result_names()` predefines variables to be used in a result set to follow. The variables must be previously declared, from which the column data types are ascertained. This assigns the meta data but does not send any results. The `result()` function sends its parameters as a single row of results. These parameters should be compatible with those in the previous `result_names()` . The `end_results()` function can be used to separate multiple result sets. The `result_names()` can then be used to alter the structure of the next result set.

The `result_names()` call can be omitted if the application already knows what columns and their types are to be returned.

See Also:
`result()` , `result_names()` , `end_result()`

11.5. Result Sets and Array Parameters

A procedure may be called with array parameters, c.f. SQLParamOptions. Each call can yield multiple result sets.

The SQLMoreResults function is used to get from one result set to the next and from one procedure call to the next. One may have to call this function an indeterminate number of times before all results from a procedure with array parameters have been received.

Each procedure return is marked with SQL_SUCCESS_WITH_INFO with SQL state 'PMORE'. The next SQLFetch will retrieve the first row of the first result set of the next procedure invocation.

11.6. Exception Semantics

Exceptions are of two types: Not Found and SQLSTATE. A not found exception occurs when a select - into or open statement finds no row or when a fetch statement reads past the last row of a cursor. A SQLSTATE exception may result from any operation, typically a manipulative SQL statement. The SQLSTATE '4001', deadlock is an example of this. A user-written procedure may signal a user defined exception with the signal function.

Virtuoso/PL supports PSM 96 style exception handlers. These allow catching specific SQL states or ranges of SQL states, invoking a specific block of code when the state is signalled from within the scope of the handler. The handler may propagate the exception to an outer handler or transfer control to any appropriate point in the containing procedure.

An unhandled exception will cause the procedure where it is detected to return the exception to its caller. If the caller is another procedure that has a handler for the specified exception that procedure invokes the handler. If the caller is a call statement issued by a client, the client gets the SQLSTATE and the SQLExecute function called by the client returns SQL_ERROR and the client application may retrieve the SQLSTATE and message with the SQLError function.

A SQLSTATE is any short string used to identify an error or exception condition. The system itself generates certain predefined SQLSTATE's for error conditions. Applications may add other states.

See the DECLARE HANDLER, whenever statement and signal function for an example of exception handling.

11.7. Virtuoso/PL Syntax

11.7.1. Create Procedure Statement

```
CREATE PROCEDURE NAME (parameter , parameter...) [RETURNS data_type]
{ statement ... }

parameter: parameter_type name data_type opt_default

parameter_type: IN | OUT | INOUT

opt_default: | DEFAULT literal | := literal
```

The create procedure statement actually performs a "create or replace" type operation. The create procedure statement compiles and stores a Virtuoso/PL procedure. The procedure text is first parsed and compiled into Virtuoso virtual machine code and if the compilation is successful the text is stored into the SYS_PROCEDURES table. This table is read at startup. Stored procedures are thus always available for use and need be defined only once. New procedures created with the same name as existing procedures automatically replace their predecessor.

See Also:

CREATE PROCEDURE Syntax - External hosted procedures

```
CREATE PROCEDURE FIBO (IN X INTEGER)
{
    IF (X < 2)
        RETURN X;
    ELSE
        RETURN (FIBO (X - 1) + FIBO (X - 2));
}

CREATE PROCEDURE CFIBO (IN X INTEGER)
{
    DECLARE RES INTEGER;

    RES := FIBO (X);

    RESULT_NAMES (RES);

    RESULT (RES);
}
```

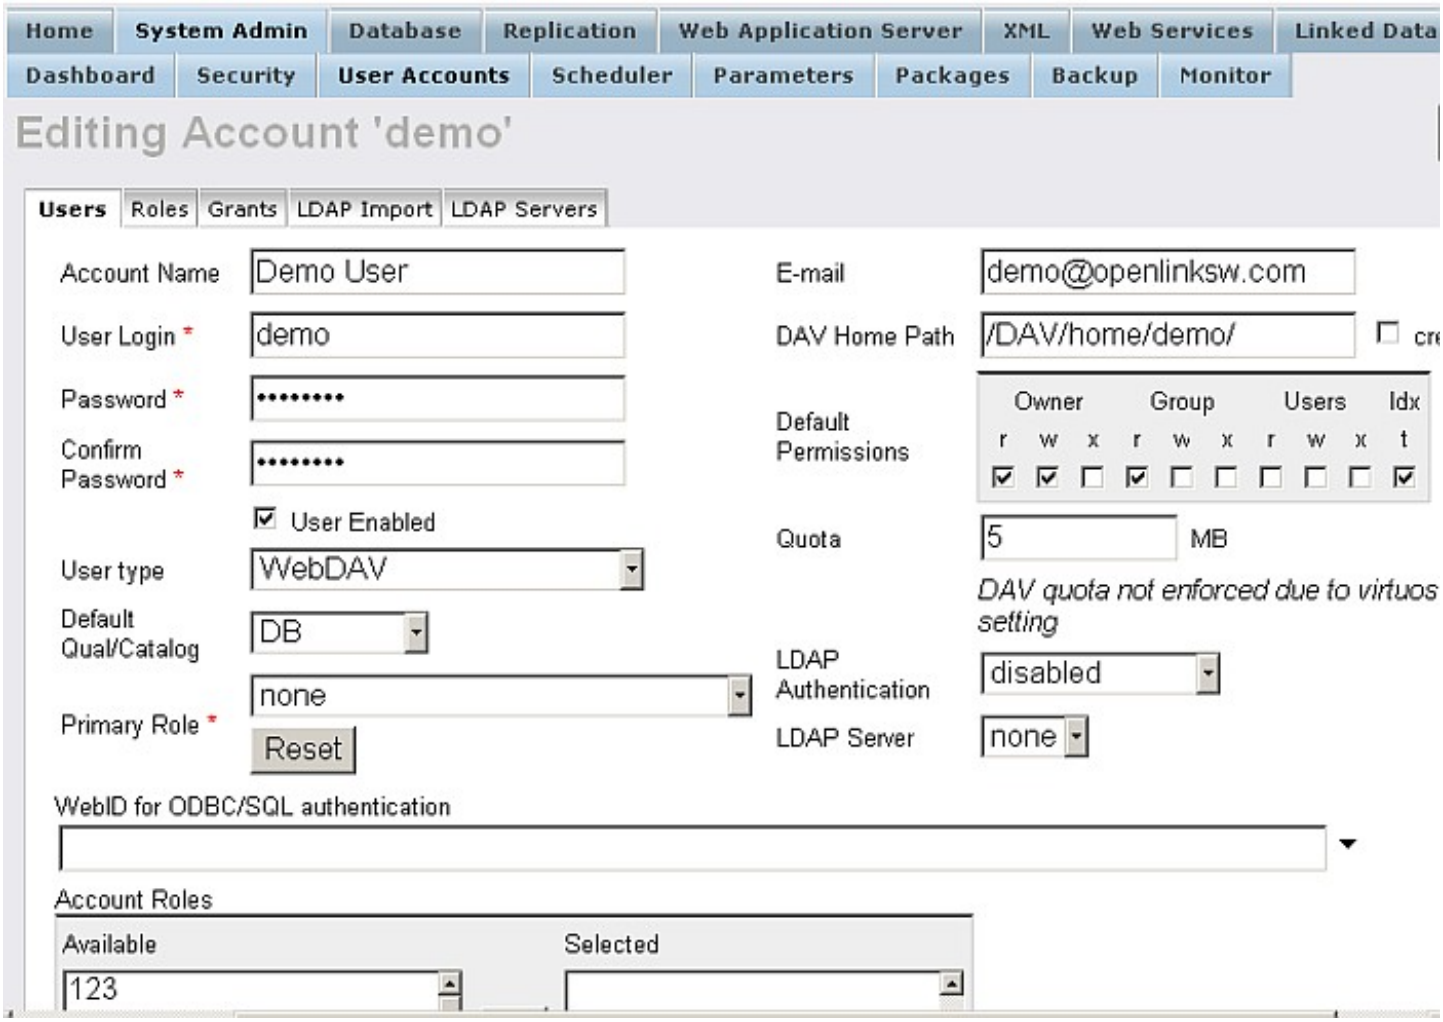
11.7.2. Grant Execute Statement

```
GRANT EXECUTE ON procedure_name TO "{USER | ROLE}" ;
```

The identifier quote character (double quotes) is important usage information since it indicates that the USER or ROLE has a literal identifier. Just as a reference (e.g., URL or URI) has the identifier quote characters "<" and ">" .

The grantee should have SQL rights in order execution of procedure to be granted to this user. The rights can be set from Conductor->System Admin->User Accounts->Account->Edit->User Type:

Figure 11.1. User Type



Example

```
SQL>create procedure DB.DBA.SimplePrint (in txt varchar)
{
 return sprintf('Output is %s', txt);
}
;

Done. -- 0 msec.

SQL>grant execute on DB.DBA.SimplePrint to "demo";

Done. -- 0 msec.

SQL>use demo;

Done. -- 0 msec.

SQL>select DB.DBA.SimplePrint('Virtuoso');

callret
VARCHAR
_______________________________________________________________________________

Output is Virtuoso

1 Rows. -- 0 msec.
```

11.7.3. Stored Procedures as Views & Derived Tables

Virtuoso allows using a stored procedure result set in place of a table. A view may also be defined as a stored procedure. This

provides smooth integration to external procedural logic in queries.

When a procedure appears as a table, the procedure is called and its result set is inserted into a temporary space. Processing continues from that point on as if the data came from a table.

See Also:
For more information about Store Procedures as Views & Derived Tables go to the SQL Reference Chapter

11.7.4. Keyword and Optional Procedure Arguments

Normally arguments in a procedure call are bound to formal parameters from left to right, as is the default behavior in any programming language. If a default value is specified for a parameter in the procedure definition this parameter is optional and the default value will be assigned to it if the caller does not specify a value. A call may consist of zero or more positional arguments followed by zero or more keyword arguments. A positional argument is any scalar expression. A keyword argument is marked with the syntax:

```
NAME => scalar_exp
```

This notation specifies that the expression is to be bound to the parameter NAME in the procedure declaration. The names are matched case-insensitively in all case modes. After all leading positional arguments have been bound to the matching formal parameters in the procedure definition, each keyword argument is bound to the parameter of the same name. After this all unbound formal parameters are assigned to their default values. If a parameter with no default remains unbound an error is signalled. OUT and INOUT parameters are always required, regardless of the mode of calling.

An expression can be passed as INOUT or OUT, but in that case the output value assigned by the procedure is not accessible in the caller. The output value is only accessible if the actual parameter is a variable or parameter.

Arguments of procedures are always evaluated left to right.

```
create procedure kwd (in k1 int := 111, inout k2 int, in k3 int := 333)
{
  result_names (k1, k2, k3);
  result (k1, k2, k3);
}

kwd (1,1+1,3);
-- results 1,2,3

kwd ();
-- error because inout parameters are always required

kwd (k2=>1);
-- error because a constant is not a suitable value for an inout parameter.

kwd (k2=>1+2);
-- result 111, 2, 333

kwd (k3=>3, k1=>1,k2=>1+1);
-- result 1, 2, 3

kwd (1, k2=>1+1);
-- result 1, 2, 333
kwd (1);
-- error, k2 is required
kwd (badkey=>2, k2=>2+1);
-- error, badkey not a parameter of the function

create procedure kwd2 (in k1 int , in k2 int, in k3 int)
{
  result_names (k1, k2, k3);
  result (k1, k2, k3);
}

kwd2 (k1=>1, k2=>2, k3=>3);
-- result 1, 2, 3
kwd2 (1,2,3);
-- result 1, 2, 3
```

11.7.5. if, while, for, foreach statements

```
if_statement
        : IF '(' search_condition ')' statement opt_else

opt_else
        : /* empty */
        | ELSE statement

while_statement
        : WHILE '(' search_condition ')' statement

for_statement
  :     FOR '(' for_init_statement_list ';' for_opt_search_cond ';' for_inc_statement_list ')' statement
  | FOREACH '(' data_type_ref identifier IN_L scalar_exp ')' DO statement
```

The IF statement executes the immediately following statement if the condition is true. If there is an else clause and the condition is false the statement immediately following the else keyword will be executed.

The while statement evaluates the search condition and executes the following statement if the condition is true. It does this as long as the condition is true. To exit from a loop, use goto. C-like break and continue statements are not available.

The for statement initiates the for_init_statement_list and executes the following statement until the search condition is true. After every execution of the statement it executes for_inc_statement_list. You can exit the loop with using goto syntax also.

The foreach statement executes the statement for each element from an array and sets a variable to the corresponding element of that array.

```
IF (A > B)
    A := A + 1;
ELSE
    B := B + 1;

WHILE (1 = 1) {
    A := A + 1;
}

FOR (declare X any, X := 1; X <= 2 ; X := X + 1){
    S := S + X;
}

FOR (declare X any, X := 1; X <= 2 ; ){
    S := S + X;
    X := X + 1;
}

FOR (declare X any, X := 1; ; X := X + 1){
    if (X > 2)
    goto exit_loop;
    S := S + X;
}
exit_loop:

declare X integer;
X := 1;
FOR (; X <= 2 ; X := X + 1){
    S := S + X;
}

ARR := vector (1,2);
FOREACH (int X in ARR) do {
    S := S + X;
}
```

11.7.6. compound statement

```
compound_statement
        : '{' statement_list '}'
        ;
```

```
statement_list
        : statement_in_cs
        | statement_list statement_in_cs
        ;

statement_in_cs
        : local_declaration ';'
        | compound_statement
        | routine_statement ';'
        | control_statement
        | label ':' statement
        ;

statement
        : routine_statement ';'
        | control_statement
        | compound_statement
        ;

local_declaration
        : cursor_def
        | variable_declaration
        | handler_declaration
        ;

variable_declaration
        : DECLARE variable_list data_type
        ;

variable_list
        : NAME
        | variable_list ',' NAME
        ;
```

The compound statement is the main building block of procedures. Statements in a compound statement are executed left to right, unless the flow of control is changed with a goto statement. The compound statement allows declaring local variables and exception handlers. See 'Scope Rules' above for a description of the scope of declarations.

Labeled statements (goto targets) and declarations can only occur within a compound statement.

See:

Create Procedure statement

11.7.7. goto, return statements

```
goto_statement
        : GOTO label
        ;

label   : NAME

return_statement
        : RETURN scalar_exp
        | RETURN
        ;
```

The goto statement unconditionally transfers control to the label following it. The label can be anywhere within the same procedure. It is in principle possible to jump into a block (e.g. loop body) from outside.

The return statement causes the executing procedure to return. If a return value is specified the expression is evaluated and returned as the return value of the procedure. If no return value is specified the procedure returns an undefined value.

Returning from a procedure automatically frees any resources associated with the procedure. This includes values in local variables or call by value (IN) parameters and any cursors that may be open.

See:

Create Procedure statement

11.7.8. whenever statement

```
condition
        : NOT FOUND
        | SQLSTATE STRING
        ;

handler_declaration
        : WHENEVER condition GOTO NAME
        ;
```

This declares that control should be transferred to a particular label in the procedure whenever a condition occurs within the lexical scope of the WHENEVER declaration. This is similar to the statement of the same name found in most embedded SQL implementations.

The scope of the declaration is all the lines lexically following the declaration. A previous declaration is replaced by a new declaration for the same <condition>.

```
CREATE PROCEDURE COUNT_CUSTOMERS (IN C_NAME VARCHAR)
{
    DECLARE COUNT INTEGER;

    COUNT := 0;

    DECLARE C CURSOR FOR SELECT C_ID FROM CUSTOMER WHERE C_NAME = C_NAME;

    WHENEVER SQLSTATE '4001' GOTO DEADLOCK;

    WHENEVER NOT FOUND GOTO DONE;

    OPEN C;
    WHILE (1=1)
    {
        FETCH C INTO N;
        COUNT := COUNT + 1;
    }

DONE:
    RETURN COUNT;

DEADLOCK:
    RETURN -1;
}
```

Note:
This is about the same as select count (*) from CUSTOMER where C_NAME = ?;

11.7.9. call, assignment statements

```
function_call
        : NAME '(' opt_scalar_exp_commalist ')'
        | call '(' scalar_exp ')' '('opt_scalar_exp_commalist ')'
        ;

call_statement
        : CALL NAME '(' opt_scalar_exp_commalist ')'
        | function_call
        ;

assignment_statement
        : lvalue EQUALS scalar_exp
        | lvalue '=' scalar_exp
        ;

lvalue  :  NAME
```

The call statement calls a specified procedure with the given arguments. The procedure to call is resolved at run time, i.e. the latest definition prevails, even if it has been made after the calling procedure was defined. The CALL reserved word is optional and is supported for compatibility.

If the called procedure has reference parameters (OUT or INOUT) the matching actual parameter must be a variable or parameter.

There is a computed function call form of function_call. In this, the scalar expression in parentheses following the call keyword should evaluate to a string which then identifies the function to be called.

The assignment statement sets a value to a variable. The variable must be either a local variable declared with declare or a procedure argument declared in the procedure argument list. If the variable in question is a reference parameter the assignment takes effect in the actual parameter as will, i.e. the value of the argument variable in the caller is set.

```
CREATE PROCEDURE COMPUTED_CALL (IN Q INTEGER)
{
    DECLARE FN VARCHAR;

    FN := 'F';

    --- CALL FUNCTION FF WITH ARGUMENT 11.
    R := CALL (CONCATENATE (FN, 'F')) (11);
}
```

11.7.10. open, fetch, close, select ... into statements

```
SELECT opt_all_distinct selection
    INTO target_commalist
    table_exp
    with_opt_cursor_options_list
    ;

opt_all_distinct
        : /* empty */
        | ALL
        | DISTINCT
        ;

with_opt_cursor_options_list
        : /* empty */
        | WITH opt_cursor_options_list
        ;

cursor_option
        : EXCLUSIVE
        ;

cursor_options_commalist
        : cursor_option
        | cursor_options_commalist ',' cursor_option
        ;

opt_cursor_options_list
        : /* empty */
        | '(' cursor_options_commalist ')'
        ;

cursor_def : DECLARE NAME CURSOR FOR query_exp
           | DECLARE NAME (DYNAMIC|KEYSET|STATIC) CURSOR FOR query_exp

open_statement
        : OPEN cursor opt_cursor_options_list
        ;

fetch_statement : FETCH cursor INTO target_commalist
                | FETCH cursor (FIRST|NEXT|PREVIOUS|LAST) INTO target_commalist
                | FETCH cursor BOOKMARK scalar_exp INTO target_commalist

target_commalist
        : variable
        | target_commalist ',' variable
        ;

close_statement
        : CLOSE cursor
        ;
```

The open, fetch and close statements manipulate cursors in Virtuoso/PL statements. Cursors are declared with the declare cursor statement. The select into statement is a shorthand for a cursor declaration, open, fetch and close.

A forward-only cursor declaration is a declaration only and executing one does not take time. The open statement effectively starts the search associated with the forward-only cursor.

The forward-only cursor options used with open and select into allow controlling how the cursor sets locks on selected rows and how many rows it fetches at a time. The EXCLUSIVE option should be used if intending to update or delete a row in the cursor's evaluation. This causes selected rows to be locked with exclusive (write) locks.

```
The statements:

{
    DECLARE CR CURSOR FOR SELECT C_NAME FROM CUSTOMER WHERE C_ID = ID;
    OPEN CR;
    FETCH CR INTO NAME;
    CLOSE CR;
}

and

SELECT C_NAME INTO NAME FROM CUSTOMER WHERE C_ID = ID;

have the same effect.
```

See:
the TPC C Bench Marking chapter for more examples.

11.7.11. FOR Select Statement

```
<for statement> ::=
     FOR <query exp> DO statement
```

The FOR statement provides a compact notation for iterating over the result set of a cursor. The body is executed once for each row in the query expression's result set. The result columns produced by the query expression are accessible as variables of the same name inside the body. All result columns do therefore have to be named with the AS declaration if they are not simple columns, in which case the name defaults to the column's name.

The body can be exited in mid loop with a goto. The cursor of the FOR does not have to be specifically closed or opened. FOR statements can be freely nested. If a WHENEVER NOT FOUND declaration is in effect before the FOR it will be canceled by it, so that it is not in effect after the loop's body.

Example 11.2. Examples

```
for select C_NAME, sum (O_VALUE) as value  from CUSTOMER, ORDER group by C_NAME DO
  {
    result (C_NAME, value);
  })
```

The equivalent code is

```
declare C_NAME, value any;
whenever not found goto done;
declare cr cursor for select ....;
open cr;
while (1) {
  fetch cr into C_NAME, value;
  whenever not found default;
  ...
}
done: ;
```

The cursor and end label names are generated to be unique by the FOR expansion.

11.7.12. SET statement

```
Set_statement:
        SET option '=' scalar_exp
        | SET option OFF
        | SET option ON
        ;

option:
        ISOLATION
        | LOCK_ESCALATION_PCT
        | TRIGGERS
        | PARAM_BATCH
        ;
```

The SET statement sets an option to a value. Options may control trigger invocation, transaction isolation and other settable parameters of the engine. A SET inside a procedure takes effect inside the procedure and invoked procedures, counting from time of execution. Control must pass through the SET statement for it to take effect, i.e. SET is not a declaration. The effect of a SET does typically not persist across procedure return.

A SET given at top level, i.e. directly executed and by a client as the statement of a SQLExecute sets an option at the connection level. This may only be reversed by another SET.

The option may be:

11.7.13. SET Triggers

A value of OFF or 0 causes triggers not to be invoked even if there may be applicable triggers. This is mostly useful for controlling recursion of triggers or for debugging triggers.

The value of TRIGGERS is passed into called procedures but other options are not.

See Also:
SET statement.

11.7.14. Vectored Procedures

Note: This feature only applies to Virtuoso 7.0 and later.

A stored procedure may be declared vectored. This means that when called from a statement operating on multiple values, a single call of the procedure can take the whole batch of variable bindings the statement is operating on in a single invocation. This saves invocation and interpretation overhead, and, most importantly, allows running any SQL statements inside the procedure on multiple values at once, creating possibilities for parallelization and exploitation of locality. The vectored declaration consists of the VECTORED reserved word at the start of the procedure body.

Consider the example of a lookup table:

```
CREATE TABLE person
  (
    p_id   INT PRIMARY KEY,
    p_name VARCHAR
  );

CREATE TABLE knows
  ( p1 INT REFERENCES PERSON,
    p2 INT REFERENCES PERSON,
    PRIMARY KEY ( p1, p2 )
  );

CREATE PROCEDURE p_name
  ( IN code INT )
  RETURNS VARCHAR
  {
    VECTORED;
    RETURN
      (
```

```
            SELECT p_name
              FROM person
             WHERE p_id  = id
          ) ;
      }

SELECT  p_name (p1)
  FROM  knows
 WHERE  p2 = 123;
```

This last statement is equivalent to:

```
SELECT  p_name
  FROM  knows,
        person
 WHERE  p_id = p1
   AND  p2 = 123;
```

For non-trivial transformations, hiding the logic inside a procedure makes sense, Running the procedure vectored makes it so that efficiency is not lost. For example, if person 123 knows 1000 people, there will not be 1000 random lookups in person for the names but rather a single, vectored, merge-style lookup, accessing the rows in order of ID, saving time if the IDs are nearby each other. Furthermore, if the lookup is in READ COMMITTED isolation, the multiple lookups can be scheduled on multiple threads.

The restrictions for vectored statement bodies also apply to function bodies that are declared vectored.

A vectored procedure can be called from a non-vectored procedure. In this case, the vectored procedure simply executes on a single set of values, as if it were not vectored.

A vectored procedure can call a non-vectored procedure. When this happens, the non-vectored procedure is called once for each set of eligible values, i.e., once for the first values of the arguments, once for the second values of the arguments, and so forth.

A vectored procedure, if called from vectored code, returns a return value for each set of arguments.

A vectored procedure can have IN and OUT parameters. These have the same semantics as in single-value execution. When calling a non-vectored procedure with an OUT or INOUT parameter, the argument in the vectored caller must be declared to be of a boxed data type. (See the section on vectoring and data types below.)

11.7.15. FOR VECTORED Statement

Note: This feature only applies to Virtuoso 7.0 and later.

```
FOR VECTORED
  ( {IN|OUT} <variable> <data_type> [ := <value>],
    ...
  )
  <compound_statement>
```

The FOR VECTORED statement allows executing a block of code on several sets of variable bindings at once. The benefit of this is that any database operations in such a block can be run on multiple sets of parameters at once, allowing exploitation of locality and, in some cases, running the operation on different bindings on different threads. Additionally, if vectored procedures are called from inside such a block, the call is made with multiple bindings for the parameters. The input variables of FOR VECTORED are initialized from an array of scalar values. The statements inside the body are then executed vectored, as if the operation were first made on all the first values of the vectors, then on the second values, and so forth. Operations combining values from different places in the vectors are not possible in the FOR VECTORED body, but, since vectored results can be seen as arrays after the return of FOR VECTORED, any aggregation or comparison between values in different positions of the same vector can be done after the FOR VECTORED, simply accessing different elements of the arrays produced.

The FOR VECTORED statement communicates with its environment through a list of input and output variables. The input variables are marked with the syntax:

```
IN <variable> <data_type> := <value>
```

The <value> must be an expression evaluating to an array. The data type must correspond to the element type of the array. When multiple input variables are specified, the arrays initializing each must be of equal length.

An output variable is marked with:

```
OUT <variable> := <value>
```

The variable must be declared in a context outside of the FOR VECTORED statement. The value of the variable will be an array where each value of the vectored expression <value> is represented as a separate value.

Variables declared outside of a FOR VECTORED statement are visible in the body of FOR VECTORED and they appear as a single value for all rows of the vectored section.

Consider the task of pair-wise adding the elements of two arrays:

```
CREATE PROCEDURE a_add
  (
    IN  a1  INT ARRAY ,
    IN  a2  INT ARRAY
  )
  {
  DECLARE  res  INT ARRAY ;
  res := make_array (LENGTH (a1, ' any' );
  FOR (i := 0; i < LENGTH (a1); i := i + 1)
    res[i] := a1[i] + a2[i];
  RETURN res;
}
```

This can be expressed as:

```
CREATE PROCEDURE a_add_v
  (
    IN  a1  INT ARRAY ,
    IN  a2  INT ARRAY
  )
  {
    DECLARE  res  INT ARRAY;
    FOR VECTORED
      ( IN   n1  INT  := a1 ,
        IN   i2  INT  := a2 ,
        OUT  res      := r
      )
      {
         DECLARE  r  INT ;
         r := i1 + i2 ;
      }
    RETURN res;
  }
```

The two procedures are identical in function. The second will make use of vector instructions in the host CPU, if available, and will incur less interpretation overhead, since the SQL run time will not need to run a loop. In practice, substantial benefit, up to an order of magnitude, can be had from vectored execution with database operations exhibiting significant locality. Bulk loads and bulk lookups are a typical example.

11.7.16. Limitations on Vectored Code

Note: This feature only applies to Virtuoso 7.0 and later.

The body of FOR VECTORED or a vectored procedure may contain arbitrary Virtuoso PL, except for LOOPs and backward GOTOs. Conditional expressions and statements are allowed, as well as any subqueries or DML statements. Looping over a cursor is not allowed, since this is a loop, but scalar subqueries and selecting-into-variables in *SELECT ... INTO* is allowed. Exception handlers are not allowed inside, but an exception handler outside of FOR VECTORED will catch errors signaled from inside FOR VECTORED. FOR VECTORED statements may not be nested and may not occur in the body of a vectored procedure. The handler, being itself not in vectored code, will not be able to see which specific value in a vectored section gave rise to the exception.

11.7.17. Data Types and Vectoring

Note: This feature only applies to Virtuoso 7.0 and later.

Parameters in vectored procedures or FOR VECTORED blocks can be declared to be of the corresponding scalar data type. The vectoring is thus in most cases transparent; the variable will simply have multiple scalar values instead of one. The ANY type in a vectored code section is represented as an array of serialized values. Thus types that are represented as data structures in allocated memory (e.g., arrays, hash tables, XML elements, etc.) will not work efficiently with ANY vectored variables. In some cases (for example, with streams or dictionaries), assigning to a vectored ANY will lose the information.

Therefore, if dealing with vectors of complex data types in vectored code, the variable holding these must be declared as an ANY ARRAY. With this type, the representation will be an array of pointers to allocated memory, not an array of flat serialized values. The ANY ARRAY type must be used instead of the customary ANY in all cases involving complex values in vectored code. If dealing with vectors of simple scalars like strings or numbers, the ANY type is generally more efficient.

11.8. Execute Stored Procedures via SELECT statement

Stored SQL Procedures can be executed via SELECT statement:

```
SELECT PROCEDURE_NAME (parameter , parameter...);
```

For ex.:

```
create procedure mytest ( in ss varchar)
{
  return concat('My simple test with ', ss);
}
;

SQL> select mytest('Virtuoso');
callret
VARCHAR
_______________________________________________________________________________

My simple test with Virtuoso

1 Rows. -- 0 msec.
```

11.9. Execute Stored Procedures In Background

You can start procedure in background using the [name of the procedure][params]& syntax. This feature forks another ISQL process and leaves the other on background so there will be two separate clients running separate client connections:

```
SQL>create procedure test()
{
return 'my simple test';
}
;
Done. -- 0 msec.
SQL>test()&
SQL> Connected to OpenLink Virtuoso
Driver: 05.07.3033 OpenLink Virtuoso ODBC Driver
OpenLink Interactive SQL (Virtuoso), version 0.9849b.
Type HELP; for help and EXIT; to exit.

Done. -- 10 msec.
```

See Asynchronous Execution and Multithreading in Virtuoso/PL for background jobs execution details.

11.10. CREATE ASSEMBLY Syntax - External Libraries

External CLR libraries can be hosted inside Virtuoso by creating an assembly from the library itself using the syntax as follows:

```
CREATE ASSEMBLY <assembly_name> FROM <assembly_location>
  [WITH PERMISSION_SET = <perm>] [WITH AUTOREGISTER];
```

assembly_name - is how Virtuoso will reference the library.

assembly_location - is where Virtuoso will find the library within the CLR.

Every .NET assembly deployed inside Virtuoso will be verifiable, which means it will contain code the CLR can verify to be safe in the way it writes to memory.

Virtuoso also respects the Common Language Runtime's code access security model. By default, code does not have any permissions to create a graphical user interface, create threads, access the file system, or call unmanaged code. The only permissions implemented are those granted for in-process data access.

Administrators will control the permissions granted to assemblies using a standard .NET machine and user-level security policy. At runtime, any code accessing protected resources produces a stack walk that triggers a permissions check against that code and any code that called it.

To simplify security administration, Virtuoso supports these standard permission sets for .NET assemblies:

SAFE - This is the default permission set. It allows internal computation and data access. There is no access to resources outside of Virtuoso. Calls to unmanaged code are not allowed. Code must be verifiable.

UNRESTRICTED - Code can access any resource. Only system administrators (dba group/role) can run unrestricted code. This level allows calls to unmanaged code, and can be unverifiable.

The restricted assemblies (SAFE mode) are not permitted to execute any code that infringes upon any of the following permissions:

AspNetHostingPermission
EnvironmentPermission
FileIOPermission
IsolatedStoragePermission
ReflectionPermission
RegistryPermission
SecurityPermission
SocketPermission
WebPermissionPermission
DNSPermission
PrintingPermission
OleDBPermissionPermission
SqlClientPermissionPermission
EventLogPermission
MessageQueuePermission
ServiceControllerPermission
PerformanceCountersPermission
DirectoryServicePermission

If the assembly generates a security exception the error text will be returned to the client.

Note:

Currently on the Microsoft .Net Framework implementation supports permission sets. Virtuoso does not currently support the `EXTERNAL_ACCESS` permission set.

WITH AUTOREGISTER marks the assembly as a stored procedure, trigger, user-defined function, etc., based on custom attributes you add to your .NET code.

Assemblies are stored in the database and are therefore backed-up and restored with the data. Once assemblies are registered using the `CREATE ASSEMBLY` syntax there will be no further dependency on the library file (dll or exe) itself.

You can remove assemblies using the familiar SQL DROP statement:

```
DROP ASSEMBLY <assembly_name>;
```

See Also:

import_clr()

Example 11.3. Working with assemblies

This example is based on the tutorial HO_S_10. we start by obtaining a C# library compile from the following code (included in the tutorial):

```
using System;

[Serializable]
public class Point_10
{
  public Double x;
  public Double y;

  public Point_10 ()
    {
      x = 0;
      y = 0;
    }
  public Point_10 (Double new_x, Double new_y)
    {
      x = new_x;
      y = new_y;
    }

  public Double distance (Point_10 p)
    {
      Double ret;

      ret =  Math.Sqrt ((p.x - this.x) * (p.x - this.x) + (p.y - this.y) * (p.y - this.y));

      return ret;
    }
}
```

This gives us the Point_10 class with two constructors and one method for finding the distance between two points.

Now we must create the library reference in Virtuoso using the following:

```
DROP ASSEMBLY "myPoint";

CREATE ASSEMBLY "myPoint" as concat (http_root() , '\\tutorial\\hosting\\ho_s_10\\Point_ho_s_10.dll')
  WITH PERMISSION_SET = SAFE WITH AUTOREGISTER;
```

Now for a quick test, we will find the distance between two points:

```
SQL> select new Point_10(0,0).distance(Point_10(3,4));
callret
DOUBLE PRECISION
_______________________________________________________

               5
```

Now we will create a table with a column of type Point_10 and then insert some test data:

```
drop table CLR..Supplier_ho_s_10;

create table CLR..Supplier_ho_s_10 (id integer primary key, name varchar (20), location Point_10);

insert into CLR..Supplier_ho_s_10 (id, name, location) values (1, 'S1', new Point_10 (1, 1));
insert into CLR..Supplier_ho_s_10 (id, name, location) values (2, 'S2', new Point_10 (3, 3));
insert into CLR..Supplier_ho_s_10 (id, name, location) values (3, 'S3', new Point_10 (5, 5));
```

Now we will demonstrate how this assembly's class can be used in SQL by showing some queries on the sample data:

```
SQL> select name, s.location.x from CLR..Supplier_ho_s_10 s;
name                  callret
VARCHAR               DOUBLE PRECISION
```

```
S1                                1
S2                                3
S3                                5
```

The distances from (0, 0):

```
SQL> select name, s.location.distance(Point_10(0,0)) from CLR..Supplier_ho_s_10 s ;
name                  callret
VARCHAR               DOUBLE PRECISION
_______________________________________________________________________________

S1                    1.414213562373095
S2                    4.242640687119285
S3                    7.071067811865476
```

Now, the points that are more than 3 units away from it:

```
SQL> select name from CLR..Supplier_ho_s_10 s where s.location.distance(Point_10(0,0)) > 3;
name
VARCHAR
_______________________________________________________________________________

S2
S3
```

Example 11.4. Using CREATE ASSEMBLY

This example demonstrates the creation of trivial CLR classes and referencing them from Virtuoso.

- *lib.cs*

```
namespace lib
{
  public class t1
  {
     public static int addit (int a1, int a2) { return a1 + a2; }
  }
}
```

- *exe.cs*

```
using lib;

public class exe
{
   public static int call_addit (int a1, int a2)
   {
      return t1.addit (a1, a2);
   }

   public static void Main (String [] args)
   {
      Console.WriteLine ("result=" + call_addit (12, 13));
   }
}
```

- *compilation*

```
csc /t:library lib.cs
csc /r:lib.dll exe.cs
```

- *Now Virtuoso can use*

```
create assembly sql_lib from 'c:\sample\lib.dll'
create assembly sql_exe from 'c:\sample\exe.exe'
```

Example 11.5. Creating Assemblies with Permission Sets

These examples will use an assembly called test.dll, whose source code is:

```
using System;
using System.IO;

public class Sample
{
   public static String GetEnv ()
     {
       return Environment.GetEnvironmentVariable("PATH");
     }
}
```

The assembly will be registered using:

```
CREATE ASSEMBLY "test" from 'test.dll' WITH PERMISSION_SET = SAFE WITH AUTOREGISTER;
```

and subsequently called using:

```
SQL> select Sample::GetEnv ();
```

returning the following error for attempting to exceed the SAFE permission set.

```
*** Error 42000: [Virtuoso Driver][Virtuoso Server]CLR05: Request for the permission of type System.Secur
      mscorlib, Version=1.0.3300.0, Culture=neutral, PublicKeyToken=b77a5c561934e089 failed.
in
__udt_method_call:(BIF),
<Top Level>
at line 4 of Top-Level:
select Sample::GetEnv ()
```

Now we can try the same sample using PERMISSION_SET = UNRESTRICTED.

```
drop ASSEMBLY "test";

CREATE ASSEMBLY "test" from 'test.dll' WITH PERMISSION_SET = UNRESTRICTED WITH AUTOREGISTER;

SQL> select Sample::GetEnv ();
callret
VARCHAR
_______________________________________________________________________________

D:\Virtuoso\bin...;

1 Rows. -- 32 msec.
<
```

Unrestricted assemblies do not have any restrictions on usage.

11.11. CREATE PROCEDURE Syntax - External hosted procedures

Virtuoso provides a syntax shortcut for calling static method from hosted user defined types without first defining a Virtuoso external hosted user defined type:

```
CREATE (PROCEDURE|FUNCTION) <local_name> ([<arg_def1>, ...])
        [returns <sql_datatype>] LANGUAGE [JAVA|CLR] EXTERNAL NAME '<external_static_proc_name_literal>'

<arg_def> := [IN|OUT|INOUT] param_name <data_type_spec>

<external_static_proc_name_literal> = <external_type_name_literal>.<static_proc_name>
```

This compiles into an functional equivalent of :

```
create procedure <local_name) ([<arg_def1>, ....])
```

```
{
  declare ret any;

  exec ('
    create type <local_name>
      temporary self as ref
        static method m1 ([<arg_def1>, ....])
           returns <datatype> EXTERNAL NAME ''<static_proc_name>''
   ');

  ret := <local_name>::m1 (....);

  exec ('drop type <local_name>');

  return ret;
  }
```

For more details see CREATE TYPE and Runtime hosting chapters.

Example 11.6. CREATE PROCEDURE for a Java method:

Here is an example for CREATE PROCEDURE and the hosted Java VM:

```
create procedure get_property (in x varchar) returns varchar language java external name 'java.lang.Syste
```

Here's how that procedure is called:

```
SQL> select get_property ('java.vm.name');
callret
VARCHAR
_______________________________________________________________________________

Java HotSpot(TM) Client VM
```

Example 11.7. CREATE PROCEDURE for a CLR method:

Here is an example for CREATE PROCEDURE and the hosted CLR:

```
create procedure curr_thr_id () returns integer language CLR external name 'mscorlib/System.AppDomain.Get
```

Here's how that procedure is called:

```
SQL> select curr_thr_id();
callret
INTEGER
_______________________________________________________________________________

2156
```

11.12. Asynchronous Execution and Multithreading in Virtuoso/PL

Many application tasks benefit from parallel execution. This is specially true of I/O intensive workloads where each thread spends a large amount of time waiting for the network or disks. Typical tasks include crawling the web and importing large data sets. The whole process must not stop just because there is a file cache miss or because there is round trip latency or a name resolution delay on the net.

To this effect, Virtuoso/PL provides the async_queue object. A stored procedure may create an async_queue that will be served by a pool of worker threads. The size of this pool can be set when creating the queue.

The thread which made the queue can use the queue to pass procedure/parameter list pairs to the threads. If a thread is available, the thread will execute the request, if not, the next thread of the pool to become free will take the oldest queued item and execute it. Thus the queue is served in a FIFO fashion multiplexed over n threads.

The owner of the queue can check on the results of execution either collectively or individually. Each worker thread has its own transaction and worker threads may end up waiting for each other own database locks and can deadlock. The worker thread code is responsible for committing its own transaction and handling any deadlock retries or such.

When the thread owning the queue makes a request, a request number is returned. This number can be used to later request the return value and error status of the request. A queue cannot be persisted in a database table and cannot be passed between threads. A queue can be passed between procedures and kept in data structures such as arrays. Queue are internally reference counted and when the last reference drops the queue is freed. If a queue is freed while there is still activity on behalf of the queue, the activities that are ongoing are finished, all requests that are not started are discarded and all values and error states are discarded. The queue and associated resources are thereafter freed.

There is a pool of 20 threads that are shared among all async_queues on the system. Thus, the count of threads given for the queue is a maximum and does not guarantee that this quantity of threads be used in reality. If no thread is available in the pool, i.e. other async queues have exhausted the entire pool, the thread making the request ends up executing the item synchronously. One should take this possibility into account when deciding transaction boundaries, otherwise this is transparent and the calling thread still gets a request handle and can later check for its completion.

Queues take procedures and argument lists instead of texts of SQL statements in order to save the time of compiling the text. It is desirable for best performance to supply the name of the procedure in its full form, with full qualification and matching case.

Consider the following code samples:

```
create table aqi (n int);

-- The worker procedure. Insert one row and commit.

create procedure INS1 (in n int)
{
  --dbg_obj_print ('ins1 ', n);
  insert into AQI (N) values (n);
  commit work;
  return '22';
}

create procedure taq1 (in x int, in thrs int := 1)
{
  declare aq, res, err any;
  declare n int;
  aq := async_queue (thrs);
  for (n:= 0; n < x; n:=n+1)
    {
      res := aq_request (aq, 'DB.DBA.INS1', vector (n));
    }
  return (aq_wait (aq, res, 1, err));
}

-- This procedure makes a queue with a given number of worker threads, then makes a set of requests and w
of the last one. Note that this is not necessarily the last to complete if there are multiple threads ser
```

11.12.1. Synchronization

It is possible to add requests to a queue at all times. It is also possible to check for the result of any request made so far, by either blocking to wait for it or just checking its status.

```
aq_wait (in aq any, in req_no int, in block int, out err any) returns any
```

The aq_wait function takes the queue, a request number returned by aq_request, a blocking flag and an output parameter for the error state.

If there was no error, the error state is set to 0. If the procedure was undefined, the error state is set to 2. If there was a SQL state signalled from the procedure called on the worker thread, the error state is set to an array of three elements: The integer 3, the SQL state string and the text of the message. If aq_wait is terminated by an external event, then an error indicating this is signalled and the state waited for is lost. This can only happen when all transactions are killed by shutdown or going to a single user state.

If the blocking flag was zero and the request was not complete, then the error output parameter is set to 1 and 1 is returned.

Once aq_wait has retrieved a state, the state is no longer retained in the queue.

The aq_wait_all function allows waiting for all activity to complete but discards individual return states. If some of running activities is terminated by sql error, this error will be raised in the thread executing aq_wait_all function call.

Note that it is possible to get a deadlock between the requesting thread and a worker thread and that this deadlock cannot be detected by the database engine since this does not involve a cycle in database locks themselves. Thus, aq_wait signals an error if the thread calling it holds database locks. Manually committing or rolling back before calling aq_wait is necessary if the thread can belong to a transaction that holds locks.

Thus, it is most practical to explicitly commit all work on the requesting thread before calling aq_wait or aq_wait_all.

```
create procedure taq_all (in x int, in thrs int := 1)
{
  declare aq, res, err any;
  declare n int;
  aq := async_queue (thrs);
  for (n:= 0; n < x; n:=n+1)
    {
      res := aq_request (aq, 'DB.DBA.INS1', vector (n));
    }
  aq_wait_all (aq);
}

-- This procedure is guaranteed to wait for all requests to be completed but will discard individual erro
```

11.13. Performance Tips

11.13.1. Remember the following:

- Reference parameters (inout and out) are faster then value parameters (in).
- Use cursors and positioned delete/update (where current of) for read-modify transactions instead of a select .. into and searched update.
- Make an EXCLUSIVE read in read-modify transactions.
- When using ORDER BY and wishing to use a particular index, specify ALL key parts of the index, including those that have a '=' condition. If you want to have descending order using an index, specify DESC on ALL key parts.

11.14. Procedures and Transactions

A procedure call executed by a client is just like any other SQL statement. It executes in the context of the client's active transaction. If the connection is in autocommit mode the transaction is automatically committed if the procedure returns successfully and rolled back if the procedure returns with an error. If the connection is in manual commit mode, a possible procedure error has no effect on the client's transaction, unless the error is a transaction error, e.g. timeout or deadlock.

For best performance, we recommend using procedures in autocommit mode. In this way, a single client-server exchange will suffice to carry out the whole transaction. This will also conveniently roll back the transaction if the procedure exited as a result of an unhandled SQLSTATE or a 'not found' condition.

Procedures can commit or rollback transactions using commit work and rollback work statements.

11.15. Distributed Transaction & Two Phase Commit

2PC is an acronym for 2 Phase Commit. This is a protocol by which data being committed to a database is committed in two phases. In the first phase, the transaction processor checks that all parts of the transaction can be committed. In the second phase, all parts of the transaction are committed. If any part of the transaction indicates in the first phase that it cannot be committed, the second phase does not occur. ODBC does not support two-phase commits.

Transactions in SQL databases are expected to have "ACID" features: Atomicity, Consistency, Isolation, Durability. A two-phase commit (2PC) protocol is needed for guaranteeing ACID properties of transactions which involve changing data in more than one database. This can be the case in a transaction involving tables attached from other databases or explicit access to remote databases with rexecute().

The 2PC protocol needs to have a third party Distributed Transaction Coordinator (DTC). Virtuoso supports Microsoft Transaction Server (or MS DTC).

There are two ways of using MTS-driven distributed transactions in Virtuoso. Virtuoso either initiates the transaction, or it responds to a transaction.

11.15.1. Initiating Distributed Transactions

In this case the transactions are initiated by Virtuoso itself. This causes all remote connections of linked tables to be automatically enlisted in a distributed transaction controlled by MTS. To enable this, Virtuoso's transaction must be set to a special state with the 'SET' statement as follows:

```
SET MTS_2PC=1;
```

This statement turns distributed transaction support on. All transactions started on remote databases shall automatically be enlisted as branches of a distributed transaction managed by MS DTC. The effect of SET, in this case, lasts until the commit or rollback of the transaction. The SET statement should be at the beginning of the transaction, before any distributed operations are undertaken.

Example of money transfer from one attached table to another:

```
CREATE PROCEDURE TWOPC_TRANSFER_MONEY(IN person_id INTEGER)
{
  IF (MTS_STATUS('MTS') = 'disconnected') -- check connection to MS DTC
  {
    MTS_CONNECT(0); -- connect to MS DTC
  }
  SET MTS_2PC=1; --  transaction of this procedure is now in distributed
  MTS_SET_TIMEOUT (1000); -- 1sec timeout on distributed transactions
  UPDATE linked_account1 SET amount=amount+100 WHERE id=person_id;
  UPDATE linked_account2 SET amount=amount-100 WHERE id=person_id;
  commit work;
}
```

This money transfer is under 2PC control of MTS. If one of the two participating databases crashes (or rolls back due to deadlock or timeout), Virtuoso will roll back the whole distributed transaction.

Note that if a transaction modifies the local Virtuoso database, and not more than one remote database, 2 phase commit is not needed for guaranteeing integrity.

Deadlocks are detected for local transactions using a wait graph. Deadlocks are detected for distributed transactions based on timeouts. Use mts_set_timeout() for explicitly setting a timeout. See MS DTC for a definition of timeouts.

11.15.2. Responding to Distributed Transactions

In this situation a distributed transaction is initiated by an ODBC client of Virtuoso. The application enlists one or more Virtuoso hdbcs in an OLE/DB distributed transaction, and then works with that hdbcs and commits or rolls back the distributed transaction.

c++ example:

```
/* begin of example */
  ITransaction* transaction;
  ITransactionDispenser* disp;
  HRESULT hr =
      DtcGetTransactionManager (0, 0, &IID_ITransactionDispenser, 0, 0, 0,
      &disp);
  hr = disp->BeginTransaction (0, ISOLATIONLEVEL_ISOLATED,
      0, 0, &transaction); /* initialize transaction */
  SQLSetConnectOption (hdbc1, SQL_COPT_SS_ENLIST_IN_DTC,
      (DWORD) transaction); /* enlist 1st hdbc in transaction */
  SQLSetConnectOption (hdbc2, SQL_COPT_SS_ENLIST_IN_DTC,
      (DWORD) transaction); /* enlist 2nd hdbc in transaction */

  ..... /* some work with ODBC connections */

  transaction->Commit (0, 0, 0); /* commit the transaction */
/* end of example */
```

If a Virtuoso connection is enlisted into a distributed transaction managed by MS DTC, and a Virtuoso statement executed in this transaction accesses attached tables, or otherwise uses other databases, then Virtuoso automatically enlists these remote databases into the original distributed transaction. If the remote database does not support MS DTC, then it signals the special error (see error list below).

For more information, see Microsoft's documentation for MTS and OLE DB.

If you want Virtuoso to start connected to MTS, add the following string in the [VDB] section of virtuoso.ini file:

```
UseMTS = 1
```

See also:
mts_connect , mts_status , mts_set_timeout , mts_get_timeout .

11.15.3. 2PC Log & Recovery

If one branch of a distributed transaction crashes during the second phase of a commit, the recovery cycle will be performed during the next start up of the server. Information about a distributed transaction is stored in the transaction log file.

When Virtuoso connects to MS DTC, it creates a guid.bin file in the working directory. This file contains a unique ID of the server and is require for the recovery cycle.

11.15.4. Error Codes

Table 11.1. 2PC & MS DTC error list

Code	Description	Possible courses
MX000	connection to MS DTC is failed	MS DTC service is not started (in case of NT4.0 MTS is not started).
37100	MTS support is not enabled	Current or involved in distributed transaction database has not connected to MS DTC.

11.16. Triggers

A trigger is a procedure body associated with a table and an event. A trigger can take effect before, after or instead of the event on the subject table. Several before, after or instead of triggers may exist for a given event on a given table, which can be fired in a specified order.

Triggers are useful for enforcing integrity rules, maintaining the validity of data computed from other data, accumulating history data etc.

A trigger body has no arguments in the sense a procedure does. A trigger body implicitly sees the columns of the subject table as read-only parameters. An update trigger may see both the new and old values of the row of the subject table. These are differentiated by correlation names in the REFERENCING clause.

Triggers are capable of cascading; the code of a trigger may cause another trigger to be activated. This may lead to non-terminating recursion in some cases. Triggers may be turned off either inside a compound statement or inside a connection with the SET TRIGGERS OFF statement.

An update trigger may have a set of sensitive columns whose update will cause the trigger code to be run. Update of non-sensitive columns will not invoke the trigger. If no column list is specified any update will invoke the trigger.

11.16.1. The CREATE TRIGGER statement

Triggers can be defined to act upon a table or column and fire upon:

UPDATE
INSERT
DELETE
at the following times during the operation on a table or column:

BEFORE

AFTER

INSTEAD OF

Triggers have a unique name which is qualified by the current catalog and owner. The trigger name is only really relevant for the purposes of dropping triggers. Triggers operate on a table or column which must be adequately qualified.

The trigger body has read-only access to the values of the data manipulation operation that triggered the trigger. In the case of an update statement it has access to both old and new values for each effected column. These values cannot be changed directly. If the trigger is to influence any data in a table, even from the current operation, it must be achieved by another SQL statement. The REFERENCING clause allows specifying a correlation name for new and old values of columns. By default, the new values are seen under the column names without a correlation name. If old values of updated columns are needed, the REFERENCING OLD AS <alias> will make <alias>.<column> refer to the old value.

Triggers defined to make further operations within the same or other table may fire further triggers, or even the same trigger again. Care must be taken to understand the implications of this and when triggers cane be allowed to continue firing after the current trigger. For example, an after update trigger that makes a further update to the same table will fire the same trigger again and may continue looping in this way endlessly. The `SET TRIGGER` statement can be issued to control this:

SET TRIGGERS on; -- (default state) further triggers within this transaction are allowed to fire.

SET TRIGGERS off; -- further triggers within this transaction are disabled.

A table may have more than one trigger. Their execution order can be specified using the ORDER clause. Each trigger gets an order number, triggers are called starting at the lowest order number in ascending order.

Syntax:

```
CREATE TRIGGER NAME action_time event ON q_table_name
  opt_order opt_old_ref trig_action

action_time
        : BEFORE
        | AFTER

event
        : INSERT
        | UPDATE opt_column_commalist
        | DELETE

opt_order
        | ORDER INTNUM

opt_old_ref
        | REFERENCING old_commalist

trig_action
        : compound_statement

old_commalist
        : old_alias
        | old_commalist ',' old_alias

old_alias
        : OLD AS NAME
        | NEW AS NAME
```

Example 11.8. Creating a simple trigger

This trigger is a simple example of one that would cause an endless loop if further triggering were not disabled.

```
create trigger update_mydate after
   update on mytable referencing old as O, new as N
{
  set triggers off;
  update mytable
    set
      previousdate = O.mydate,
      mydate=now()
```

```
    where id=N.id;
}
;
```

The trigger makes aliases for the values of the column that are part of the SQL manipulation transaction that will be in progress, hence the values of the columns can be accessed as "O.column" and "N.column" for old and new values respectively.

The set statement is scope to the procedure or trigger body where it occurs, plus procedures called from there , thus when the trigger finishes no other triggers are effected by it.

Example 11.9. Creating a simple trigger using INSTEAD OF

This trigger example will show how INSTEAD OF can be used to intercept the values of an insert statement and re-write it. In this case the purpose is to deliberately truncate VARCHAR inserts to prevent an error if the data type bounds are exceeded:

First we create a test table with a 30 character limitation in one of the columns:

```
SQL>create table test_trunc (
      id integer not null primary key,
      txt varchar (30)
      )
    ;

Done. -- 10 msec.
```

Then we attempt to insert 33 characters into it with the following results:

```
SQL>insert into test_trunc (id, txt)
      values (1, 'aaaaaaaaaabbbbbbbbbbccccccccccxxx');

*** Error 22026: [Virtuoso ODBC Driver][Virtuoso Server]SR319: Max column length (30) of column [txt] exc
```

Now we make a trigger to fire instead of insert statements that can perform some custom error correction, in this case we simply want to chop-off any extra characters that will cause an insert to fail.

```
SQL>create trigger test_trunc_it
      instead of insert on test_trunc
        referencing new as N
    {
      set triggers off; -- we do not want this looping...
      insert into test_trunc (id, txt) values (N.id, left(N.txt, 30));
    }
    ;

Done. -- 10 msec.
```

We perform the same test insert, now without errors:

```
SQL>insert into test_trunc (id, txt)
  values (1, 'aaaaaaaaaabbbbbbbbbbccccccccccxxx');

Done. -- 10 msec.
```

And to see what we have in the database, a quick select:

```
SQL> select * from test_trunc;
id                txt
INTEGER NOT NULL  VARCHAR
_____________________________________________________

1                 aaaaaaaaaabbbbbbbbbbccccccccccc

1 Rows. -- 20 msec.
```

11.16.2. Triggers on Views

In virtuoso you can create a trigger on a view. To accomplish this there is only one condition: The first trigger for a given type of event (INSERT/DELETE/UPDATE) must be an INSTEAD OF trigger. After such a trigger is defined then any type of triggers (AFTER/BEFORE) can be added.

Example 11.10. Creating a trigger on view

We will make two tables and an union view for them. Then we will create a trigger which inserts a new record in one of the tables according to values.

First lets create the tables and the view.

```
create table first_table(
  id integer not null primary key,
  txt varchar
);

create table second_table(
  id integer not null primary key,
  txt varchar
);

create view all_tables (id,from_table,txt)
as select id,'first',txt from first_table
union all
select id,'second',txt from second_table;
```

Now lets create a trigger instead of insert for the view and insert some data.

```
create trigger insert_all_tables
  instead of insert on all_tables referencing new as N{
    if(N.from_table = 'first' or N.from_table = 'all')
      insert into first_table (id,txt) values(N.id,N.txt);

    if(N.from_table = 'second' or N.from_table = 'all')
      insert into second_table (id,txt) values(N.id,N.txt);
  };

  insert into all_tables (id,from_table,txt) values (1,'first','into first');
  insert into all_tables (id,from_table,txt) values (2,'second','into second');
  insert into all_tables (id,from_table,txt) values (3,'all','into all');

  select * from all_tables;

  id       from_table  txt
  INTEGER  VARCHAR  VARCHAR
  _____________________________________________________________________________

  1        first    into first
  3        first    into all
  2        second   into second
  3        second   into all
```

You can see that the trigger inserted the data in the two tables according the value of from_table.

11.16.3. The DROP TRIGGER statement

```
DROP TRIGGER qualified_name
```

This drops a trigger of the given name. The name may optionally have a qualifier and owner, in which case these should be the qualifier and owner of the subject table of the trigger. Identical trigger names may exist for identically named tables in different namespaces.

11.16.4. Triggers and Virtual Database

Triggers may be defined on tables residing on remote databases. The semantic of triggers is identical but will of course only take place when the manipulation takes place through the Virtuoso defining the triggers. Trigger bodies may reference remote tables just as any other procedure bodies can. Note that triggers can be used for replication, i.e. one may define a local change to be mirrored to a remote table using a trigger.

Consider an application with a warehouse supplying orders. There is a total value of all orders kept at the warehouse level and there is the total value of all order lines kept at the order level. When an order line is added, both the order value and consequently the total order value are updates. These values are maintained for insert, update and delete of order line. On the other have, when an order is deleted, all corresponding order lines must be deleted.

These rules are maintained with the below set of triggers.

```
drop table T_WAREHOUSE;

drop table T_ORDER;

drop table T_ORDER_LINE;

create table T_WAREHOUSE (W_ID integer default 1,
                          W_ORDER_VALUE float default 0,
                          W_DATA varchar,
                          primary key (W_ID));

create table T_ORDER (O_ID integer not null primary key, O_C_ID integer,
                      O_W_ID integer default 1,
                      O_VALUE numeric default 0,
                      O_MODIFIED datetime);

create table T_ORDER_LINE (OL_O_ID integer,
                           OL_I_ID integer,
                           OL_QTY integer,
                           OL_MODIFIED timestamp,
                           OL_I_PRICE float default 1,
                           primary key (OL_O_ID, OL_I_ID));

create index OL_I_ID on T_ORDER_LINE (OL_I_ID);

create trigger AMT_INS after insert on T_ORDER_LINE
{
  update T_ORDER
    set O_VALUE = O_VALUE + OL_QTY * OL_I_PRICE
    where O_ID = OL_O_ID;
}

create trigger AMT_DEL after delete on T_ORDER_LINE
{
  update T_ORDER
    set O_VALUE = O_VALUE - OL_QTY * OL_I_PRICE
    where O_ID = OL_O_ID;
}

create trigger AMT before update on T_ORDER_LINE referencing old as O
{
  update T_ORDER
    set O_VALUE = O_VALUE - O.OL_QTY * O.OL_I_PRICE + OL_QTY * OL_I_PRICE
    where O_ID = OL_O_ID;
}

create trigger W_VALUE before update (O_VALUE) on T_ORDER
     referencing old as O, new as N
{
  update T_WAREHOUSE
    set W_ORDER_VALUE = W_ORDER_VALUE - O.O_VALUE + N.O_VALUE
    where W_ID = O.O_W_ID;
}

create trigger O_DEL_OL after delete on T_ORDER order 2
{
```

```
  set triggers off;
  delete from T_ORDER_LINE where OL_O_ID = O_ID;
}

create trigger O_DEL_W  after delete on T_ORDER order 1
{
  update T_WAREHOUSE
    set W_ORDER_VALUE = W_ORDER_VALUE - O_VALUE
    where W_ID = O_W_ID;
}

create procedure ol_reprice_1 (in i_id integer, in i_price float)
{
  declare id integer;
  declare cr cursor for
    select OL_I_ID from T_ORDER_LINE;
  whenever not found goto done;
  open cr;
  while (1) {
    fetch cr into id;
    if (id = i_id)
      update T_ORDER_LINE set OL_I_PRICE = i_price where current of cr;
  }
 done:
  return;
}

create procedure ol_reprice_2 (in i_id integer, in i_price float)
{
  declare id integer;
  declare cr cursor for
    select OL_I_ID from T_ORDER_LINE order by OL_I_ID;
  whenever not found goto done;
  open cr;
  while (1) {
    fetch cr into id;
    if (id = i_id)
      update T_ORDER_LINE set OL_I_PRICE = i_price where current of cr;
  }
 done:
  return;
}

create procedure ol_del_i_id_2 (in i_id integer)
{
  declare id integer;
  declare cr cursor for
    select OL_I_ID from T_ORDER_LINE order by OL_I_ID;
  whenever not found goto done;
  open cr;
  while (1) {
    fetch cr into id;
    if (id = i_id)
      delete from T_ORDER_LINE where current of cr;
  }
 done:
  return;
}
```

Compatibility:

Virtuoso triggers are modeled after SQL 3. Omitted are the FOR EACH STATEMENT and related OLD TABLE AS phrases as well as the WHEN in the trigger body. The implementation is otherwise complete.

11.17. Character Escaping

The C style escape character can be used to include special characters inside literals. The backslash character, '\', followed by an octal character code or a special character provides a notation for characters that are normally not typable in a string literal such as tab or crlf. Backslash support can be turned on or off at the statement level, the connection level or server default level.

11.17.1. Statement Level

If you want to activate or deactivate the backslash support in a stored procedure you can use the following two special comments (on a separate line) :

```
--no_c_escapes+
```

turns the backslash escaping support off (insert into x values ('c:\test') will result in 'c:\test' in the column

```
--no_c_escapes-
```

turns the backslash escaping support on. (same as above will insert 'c:test' in the column.)

11.17.2. Connection Level

The switch SET SQL_NO_CHAR_C_ESCAPE can be set to 'on' or 'off' to respectively turn backslash support on or off for the current connection

There is an ODBC connection attribute that can be set for the same effect in an ODBC connection. SQLGetConnectAttr/SQLSetConnectAttr with option ID of 5002 takes values 0 or 1 to facilitate this

11.17.3. Server Default

SQL_NO_CHAR_C_ESCAPE=0/1 can be set in the "Client" section of the virtuoso.ini file to set the connection default backslash handling behavior. The default value is 0.

Note

When a 'create procedure' is executed and that mode is "ON" the procedure is stored in such a way that it will preserve the setting for it's text no matter what the current default is.

11.18. Virtuoso/PL Scrollable Cursors

Virtuoso/PL supports scrollable cursors, providing functionality similar to the ODBC scrollable cursor support. Scrollable Cursor support extends the basic (forward-only) syntax of DECLARE CURSOR and FETCH to support the various fetch directions & cursor modes. The Virtuoso/PL scrollable cursors always operate with a rowset size equal to 1. The keyset size (where applicable) is as per the default.

Note:

If a Virtuoso/PL cursor is declared forward only it supports only FETCH .. NEXT scroll direction. The FETCH defaults its direction to NEXT (if omitted) so this is how the syntax extensions to DECLARE CURSOR & FETCH interoperate with the forward-only cursors syntax.

11.18.1. Declaring a Scrollable Cursor

Virtuoso/PL cursor types are specified at declaration time. Unlike the forward-only cursor declaration the scrollable cursor DECLARE CURSOR causes some actions (cursor statement preparation & cursor variable assignment). The cursor variable's value can not be copied, it should be passed only by reference in procedure calls. Scrollable cursors have an appropriate destructor, which will close the cursor when the cursor variable goes out of scope. Variables in the surrounding context are referenced similarly to the forward-only cursor.

Note:

Some types of statements do not allow other cursor types than static. For example SELECT DISTINCT will always result in a static cursor, ignoring the cursor declared type.

11.18.2. Opening a Scrollable Cursor

The OPEN on a scrollable cursor opens the cursor and sets it's position right before the first resultset row. So before taking the bookmark value at least one FETCH should be issued.

11.18.3. Fetching Data From a Scrollable Cursor

The FETCH on a scrollable cursor allows specification of a direction. If there is no more data in the specified fetch direction this causes the NOT FOUND exception to be raised, as with the forward-only cursors. In addition to that if the row on which the cursor is about to position has been deleted and the isolation level & cursor type allows detecting that, then the exception SQLSTATE 'HY109' (Row deleted) is raised.

Positioning on a bookmark is done the following way:

A bookmark value should be retrieved using the bookmark() function . The value returned by that function can be stored, copied and retrieved. This value can also survive a cursor close and reopen, even between transactions. How the cursor will behave if a bookmark from a cursor with different select statement or scroll type is used for positioning is undefined and should be avoided. On some occasions it may signal an error, on others it will position on a wrong or non-existing row. As a general rule bookmark values should be used only on the cursor from which they are generated.

The cursor should be in opened state. Now a FETCH .. BOOKMARK bm_value INTO ... can be issued with the bookmark variable.

Bookmarks can serve for persisting the cursor position in an VSP context. One can imagine a VSP page which on it's first go will execute a cursor and will show the first so-many rows. Then it can retrieve the bookmark value of the last displayed row, persist it somehow (for example as an HTTP session variable), then close the cursor and exit. On each subsequent hit it will open again the same cursor, position on the bookmark persisted and return the next, previous, first or last so-many rows.

11.18.4. Virtuoso/PL Scrollable Cursor Examples

Example 11.11. Procedure using scrollable cursor to read the keys in batches of 20

```
create procedure READ_KEYS_NEXT_20 (in mask varchar, inout bm any) returns integer
{
  --- This procedure reads the next 20 table names based on a bookmark value.
  declare cr static cursor for
      select distinct KEY_TABLE
        from DB.DBA.SYS_KEYS
        where
          KEY_IS_MAIN = 1 and
          KEY_MIGRATE_TO is NULL and
          KEY_TABLE like mask;
  declare table_name varchar;
  declare inx integer;

  inx := 1;

  -- no 'Row Deleted' (HY109) handling as the static cursors doesn't show the deleted rows.
  whenever not found goto done;
  open cr;

  -- positions on the bookmark or on the first if it is null
  -- and fetches the value into table_name
  if (bm is not null)
    {
      fetch cr bookmark bm into table_name;
      -- note that the value from fetch bookmark is omitted
      fetch cr next into table_name;
    }
  else
    fetch cr first into table_name;

  -- fetches the next 20 rows (or less)
  while (inx < 20)
    {
      result (table_name);
      inx := inx + 1;
      fetch cr next into table_name;
    }

  -- 20 rows were fetched - get the bookmark of the last row fetched
  bm := bookmark (cr);
  close cr;
```

```
  return;

done:

  -- no more rows - set the bookmark to NULL
  close cr;
  bm := NULL;
};

create procedure READ_KEYS (in mask varchar)
{
  -- the main function (mask is a mask to be applied over the select

  declare table_name varchar;
  declare bm any;

  -- it'll return a resultset with a single column
  result_names (table_name);

  -- sets the bookmark to empty
  bm := NULL;

  while (1)
    {
       READ_KEYS_NEXT_20 (mask, bm);

       -- that's the flag for no more rows
       if (bm is NULL)
         return;
    }
};

READ_KEYS ('%');
```

11.18.5. FORWARD-ONLY (traditional cursor statement) Example

Example 11.12. Procedure using forward only cursor

```
create procedure TEST_FW()
{
  declare cr cursor for select KEY_ID from DB.DBA.SYS_KEYS;
  declare inx, data integer;
  inx := 0;

  whenever not found goto done;
  open cr;
  while (1)
    {
      fetch cr into data;
      inx := inx + 1;
    }
done:
  close cr;
  result_names (data);
  result (inx);
};
TEST_FW();
```

11.18.6. DYNAMIC (traditional cursor statement) Example

Example 11.13. Procedure using dynamic cursor

```
create procedure TEST_DYNAMIC ()
{
  declare cr dynamic cursor for select KEY_ID from DB.DBA.SYS_KEYS;
  declare inx, data integer;
  inx := 0;

  whenever not found goto done;
```

```
  open cr;
  while (1)
    {
      fetch cr into data;
      inx := inx + 1;
    }
done:
  close cr;
  result_names (data);
  result (inx);
};
TEST_DYNAMIC ();
```

11.18.7. KEYSET (traditional cursor statement) Example

Example 11.14. Procedure using keyset cursor

```
create procedure TEST_KEYSET ()
{
  declare cr keyset cursor for select KEY_ID from DB.DBA.SYS_KEYS;
  declare inx, data integer;
  inx := 0;

  whenever not found goto done;
  open cr;
  while (1)
    {
      fetch cr into data;
      inx := inx + 1;
    }
done:
  close cr;
  result_names (data);
  result (inx);
};
TEST_KEYSET ();
```

11.19. Virtuoso PL Modules

Modules are packages of procedures which compile together. Procedure names in module definitions are not fully qualified names, but consist only of a single identifier that it is appended to the name of the module (which is a 3-part name) to make the 4-part module procedure name.

Module procedures do not appear in SQLProcedures output. Module names are in the same domain as the procedure names, so it is not possible to have a procedure with the same name as an existing module.

11.19.1. Syntax

```
CREATE MODULE
  m_name
{
  [PROCEDURE|FUNCTION] p_name1 (...) { ...};
  [PROCEDURE|FUNCTION] p_name2 (...) { ...};
  ...
  [PROCEDURE|FUNCTION] p_nameN (...) { ...};
}

DROP MODULE m_name;
```

Example 11.15. Procedure Modules

```
create module
  DB.DBA.MOD
{
  function MOD1 () returns varchar {
    return ('MOD1');
```

```
  };

  procedure MOD2 () {
    return concat (MOD1(), 'MOD2');
  };
};
```

This example creates a module, MOD, with 2 procedures: MOD1 & MOD2. Their fully-qualified names are DB.DBA.MOD.MOD1 and DB.DBA.MOD.MOD2.

Note the call to MOD1 in MOD2 - it is not fully qualified, but it resolves to the module procedure MOD1, instead of any procedure external to the module.

A single part procedure name in a call inside a module is first matched against procedures defined in the module. If the above example were executed by DBA (in the DB qualifier), then the below statements are equivalent:

```
select DB.DBA.MOD.MOD1()
select DB..MOD.MOD1()
```

The statement:

```
select MOD.MOD1()
```

will result in calling the DB.DBA.MOD.MOD1() only if a function DB.MOD.MOD1 does not exist. If it exists, it will be preferred over DB.DBA.MOD.MOD1 when using this notation.

11.19.2. Security

Module procedures can be granted to users. Modules can also be granted to users. Granting execute to a module is equivalent to granting execute for all of the module's procedures.

11.20. Handling Conditions In Virtuoso/PL Procedures

Condition handlers determine the behavior of a Virtuoso/PL procedure when a condition occurs. You can declare one or more condition handlers in your Virtuoso/PL procedure for general SQL conditions or specific SQLSTATE values.

If a statement in your procedure raises an SQLEXCEPTION condition and you declared a handler for the specific SQLSTATE or SQLEXCEPTION condition the server passes control to that handler.

If a statement in your Virtuoso/PL procedure raises an SQLEXCEPTION condition, and you have not declared a handler for the specific SQLSTATE or the SQLEXCEPTION condition, the server passes the exception to the calling procedure (if any). If the procedure call is at the top-level, then the exception is signalled to the calling client.

Handlers are active only for the duration of the enclosing compound statement. When an exception is thrown outside the handler's scope then this handler is never called.

11.20.1. Declaring Condition Handlers

The general form of handler declaration is:

```
DECLARE <handler_type> HANDLER FOR
        <condition> [, <condition [...]]
        <sql_procedure_statement>;
```

For compatibility handlers can be declared also as :

```
WHENEVER <condition> [GOTO <label>|DEFAULT];
```

When Virtuoso raises a condition that matches the <condition>, the <sql_procedure_statement> gets executed and when (and if) it finishes the execution continues according to the <handler_type>.

```
<handler_type>
```

CONTINUE - Specifies that after <sql_procedure_statement> completes, execution continues with the statement after the statement which caused the error.

EXIT - Specifies that after <sql_procedure_statement> completes, execution continues after the end of the compound statement that contains the declaration of the handler.

```
<condition>
```

NOT FOUND - Identifies any condition that results in SQL STATE = SQL_NO_DATA_FOUND (+100)

SQLEXCEPTION - Identifies all character SQL STATEs excluding ones starting with '01', '02' and '00'

SQLWARNING - Identifies character SQL STATEs starting with '01'. This is a shortcut for SQLSTATE '01*'

SQLSTATE [VALUE] '<sql_state_mask>' - Identifies character SQL STATEs. The <sql_state_mask> can be a full 5 character value or 0-4 characters followed by an '*'. When a '*' is present then any SQL STATE signal led which starts with the same characters as the <sql_state_mask> before the '*' will cause that handler to execute. For example the exception with SQL state '42S22' will match all the following

```
SQLSTATE <conditions> :
SQLSTATE '*' SQLSTATE '42*'
SQLSTATE '42S22'
```

Note:

Handler's call priority is determined by the number of matching characters in this mask.

```
<sql_procedure_statement>
```

This can be any allowed Virtuoso/PL statement as well as an compound statement. This statement is executed in the same procedure context as the procedure body itself, so any labels and variables in the procedure body can be used and RETURN causes the procedure to end. No handler is active while the <sql_procedure_statement> is executed. So any exception raised is passed directly to the procedure caller. The <sql_procedure_statement> can be empty resulting in the <handler_type> action being taken right after setting the __SQL_STATE & __SQL_MESSAGE variables.

When multiple active handlers <condition>s match the exception being raised Virtuoso chooses the closest to the statement raised the exception that has a largest call priority. This means that if an exception is there are two handlers with condition SQLSTATE '4*' and SQLSTATE '42*' and an exception with SQL STATE '42S22' is raised the handler with <condition> '42*' will be called.

```
WHENEVER <condition> GOTO <label>
```

is an equivalent of:

```
DECLARE EXIT HANDLER FOR <condition> GOTO label.

WHENEVER <condition> DEFAULT
```

is equivalent of:

```
DECLARE EXIT HANDLER FOR <condition> RESIGNAL;
```

The following examples demonstrate simple common handlers:

CONTINUE handler: The handler assigns a value of 1 to a local variable at_end when a NOT FOUND condition is raised. The execution then continues with the statement after the signal.

```
create procedure test1 ()
{
  declare at_end integer;

  at_end := 0;
  declare continue handler for NOT FOUND at_end := 1;

  result_names (at_end);
```

```
  result (at_end);
  signal (100);
  result (at_end);
}
```

When this procedure gets executed it returns the following result set :

```
0
1
```

EXIT handler: The handler assigns a value of 2 to a local variable at_end when a NOT_FOUND condition is raised. The execution then continues with the statement after the compound statement containing the signal.

```
create procedure test2 ()
{
  declare at_end integer;

  result_names (at_end);

  at_end := 0;
  declare exit handler for NOT FOUND at_end := 1;

    {
      result (at_end);
      signal (100);
      result (3);
    }
  result (at_end);
}
```

When this procedure gets executed it returns the following result set :

```
0
1
```

```
__SQL_STATE and __SQL_MESSAGE variables.
```

All Virtuoso/PL procedure have two variables implicitly declared :

```
declare __SQL_STATE any;
declare __SQL_MESSAGE varchar;
```

Initially they are set to 0.

When an exception is raised these variables are set as follows :

```
__SQL_STATE gets the SQL STATE (character string or integer 100 for NOT FOUND)
__SQL_MESSAGE gets the SQL MESSAGE (character) or NULL if no message.
```

Their values are preserved until the next exception overwrites them.

```
RESIGNAL statement

Syntax :
RESIGNAL [ '<new_sql_state>' ]

RESIGNAL  is a shortcut for    signal (__SQL_STATE, __SQL_MESSAGE)
RESIGNAL '<new_sql_state>' is a shortcut for     signal ('<new_sql_state>', __SQL_MESSAGE);
```

This statement resignals the current exception to the caller of the procedure.

11.20.2. Stack Trace Reporting On Sql Error Generation

When an exception occurs the Virtuoso server has the ability to provide information about the procedure call stack. It appends the call stack information to the error message text. There are also line numbers besides each level of the call stack which are a Virtuoso/PL procedure. The line numbers mark the beginning of the innermost compound statement.

The call stack reporting mode is controlled by the "CallstackOnException" option in the *Parameters* section of the Virtuoso INI file .

This parameter takes the following values:

0 (default) - Call stack reporting disabled.

1 - Call stack is reported but does not include values of arguments.

2 - Call stack is reported and contains all available information.

Call stack reporting can be a security hole because it can demonstrate internal logic of the system to the end user; this is especially important for dynamic web pages. Mode 2 is especially insecure because it may print values of function arguments that may contain confidential information.

Some client applications are unable to handle long error messages properly. Client-side APIs for ODBC and similar protocols assume that client should allocate a buffer for error message string and then ask the API to save the message string to the specified buffer of the specified size. Not all client applications work properly if a message does not fit in the buffer. If an client application you use reports an empty string instead of error message or displays a message like 'Error message is too long' then you may wish to decrease the value of the "CallstackOnException" option to keep messages shorter.

11.21. Procedure Language Debugger

Virtuoso has step by step PL debugging capabilities and a call stack trace option. When Virtuoso is running with a console or with stdout going somewhere like a file you can print debug messages directly to that using `dbg_printf()` and `dbg_obj_print()` functions.

Procedure source code can be written to an ASCII file using any text/programming editor. This file can be loaded into ISQL using the load command or directly from the command line using the ISQL batch mode:

```
isql data-source user password file
```

ISQL can then be used to test the procedures functionality. Procedures can return result sets to ISQL for data debugging purposes too. When dealing with results sets in ISQL remember to call procedures using the `CALL` keyword to ensure that ISQL outputs all result sets:

```
CALL procedure(arguments);
```

The PL procedure debugger allows you to execute procedures step-by step, or stop execution based upon a predefined condition within Virtuoso/PL procedure(s). This feature is not intended for SQL statements debugging. SQL statements are treated as atomic units of execution, it is not possible to step into these. It is possible to step over a procedure which loops over a cursor, though. Procedures are compiled with extra information for debugging, thus the speed of execution may be somewhat reduced. It is possible to step in or step over statements, however this does not apply to SQL statements. In order to start debugging on some event, breakpoints are required. The breakpoints can be global or temporary. The global breakpoint means the process will stop with or without a debug session. The temporary breakpoints are to stop execution only in the current debug session.

Procedure debugging can be activated in two ways. You can instruct Virtuoso to enable debugging information for all procedures using the PLDebug parameter in the Virtuoso INI file, or for selected procedures by including a special comment "`--pl_debug+` " at the top of the procedure. Debug information is visible only from a debugging tool such as ISQL

ISQL can be used as a procedure debugging tool. ISQL is started in debug mode using the -D switch:

```
isql <host:port> dba <dba-password> -D
```

Debugging of the server is restricted to dba privileged accounts for security reasons. The summary of the debug commands available can be viewed from typing help in the debugger. The following list will be shown:

```
DEBUG> help
OpenLink Interactive PL Debugger (Virtuoso).

Available commands:
    BREAK procedure_name [line number] - Set breakpoint at specified line or PL function
    NEXT  - Step program, proceeding through PL subroutine calls.
    INFO (THREAD|CLIENT|BREAK) - Generic command for showing things about the program/process being debug
            THREAD - Running threads
```

```
            CLIENT - Connected SQL/ODBC clients
            BREAK - Active breakpoints
     ATTACH thread_id|client_id - Attach to a running process.
     STEP  - Step PL program until it reaches a different source line.
     LIST [procedure name] [line number] - List specified procedure or line.
     WHERE  - Print backtrace of all stack frames.
     CONTINUE  - Continue PL program being debugged after breakpoint.
     PRINT variable_name - Print value of variables or arguments.
     SET variable_name new_value - Assign a specified value to a variable.
     DELETE ([breakpoint_number]|[procedure_name] [line_number]) - Delete some breakpoints.
     FRAME frame_number - Select and print a stack frame.
     FINISH  - Execute until returns.
     UNTIL line_number - Execute until the program reaches a source line greater than the current.
```

There are two debug modes: local, for issuing local breakpoints and step commands; global, for making global breakpoints.

There are two console or screen modes to debug/attach-to. These are: the global console, which allows you to issue the INFO, ATTACH, BREAK, DELETE commands; the local console, which once attached (using the ATTACH command) via the global console becomes local and all possible commands are available.

There are two syntaxes for specifying breakpoint locations, `BREAK FFFF NNN` and `BREAK FFFF` where FFFF is a name of a procedure.

Local breakpoints will interrupt execution only if there is a connected debug session. Global break points will cause the process to stop regardless.

The source identification and line number output can be controlled with a special comment in the PL code. This can be useful when you want to alter the compilers notion of the current file and line number. `--src FILENAME:LINENUMBER` can be used to reset the counters to the specified filename and line number. This is also useful for handling test coverage output - see the next section.

Example 11.16. Debugging simple procedures

Consider the following PL procedures:

```
create procedure
db.dba.test_proc1 (in b varchar)
{
  --pl_debug+
   declare c integer;
   c := 0;
   for select u_id, u_name from sys_users do
     {
       c := u_id;
     }

   c := vector (1);

   c := test_proc2 ();

   return c;
};

create procedure
db.dba.test_proc2 ()
{
  --pl_debug+
  declare x, y any;
  x := 1;
  if (x = 1)
     {
       y := x + 1;
     }
   else
     {
       y := 2;
     }
   return y;
};
```

Here is a simple debugging session on the above procedures:

```
$ isql localhost:1111 dba dba -D
Debug session established to localhost:1111
```

Display the test procedures to familiarize yourself with the lines and their line numbers.

```
DEBUG> list db.dba.test_proc1;
1 create procedure
2 test_proc1 (in b varchar)
3 {
4   --pl_debug+
5   declare c integer;
6   c := 0;
7   for select u_id, u_name from sys_users do
8     {
9       c := u_id;
10     }

DEBUG> list db.dba.test_proc1 11;
11
12   c := vector (1);
13
14   c := test_proc2 ();
15
16   return c;
17 }
18
19
20
```

put a break after for select statement.

```
DEBUG> break db.dba.test_proc1 11
Breakpoint at: procedure DB.DBA.test_proc1, line 11
```

Now, start another ISQL session to Virtuoso and run the procedure that we are debugging, DB.DBA.test_proc1('), and wait for it to hit the breakpoint. Back to the debug ISQL, get the list of breakpoints:

```
DEBUG> info thre
@1111:4 in DB.DBA.test_proc1 () at 11
```

attach to thread of interest:

```
DEBUG> attach @1111:4
1111:4
```

Find out where it stopped:

```
DEBUG> where
#0 DB.DBA.test_proc1 () at 11
#1 ?? () at 0
```

print the value of 'c' now, and continue step by step

```
DEBUG> print c
$25 "c" INTEGER (189) 4
DEBUG> next
11
DEBUG> print c
$25 "c" INTEGER (189) 4
DEBUG> next
12   c := vector (1);
DEBUG> print c
$25 "c" ARRAY_OF_POINTER (193) (1 )
DEBUG> next
13
```

step into the test_proc2 procedure:

```
DEBUG> step
14   c := test_proc2 ();
```

examine the stack

```
DEBUG> where
#0 DB.DBA.test_proc2 () at 4
#1 DB.DBA.test_proc1 () at 14
#2 ?? () at 0
```

step through the test_proc2 procedure

```
DEBUG> next
7   x := 1;
DEBUG> next
8   if (x = 1)
DEBUG> next
10       y := x + 1;
DEBUG> next
11     }
DEBUG> print y
$25 "y" INTEGER (189) 2
```

set the 'y' to be 100

```
DEBUG> set y 100
The 'y' is set to '100'.
DEBUG> next
16   return y;
DEBUG> print c
$25 "c" INTEGER (189) 100
```

continue the execution

```
DEBUG> cont
Execution resumed
DEBUG>
```

11.21.1. Branch Coverage

The Virtuoso ini file contains a parameter in [Parameters] section called TestCoverage whose value is the name of an XML file that will accumulate test coverage data.

The PLDebug switch controls the type of debugging enabled:

PLDebug = 0 - default debugging information and test coverage disabled.

PLDebug = 1 - debugging information enabled.

PLDebug = 2 - debugging information enabled, test coverage data will be written to file specified in TestCoverage Virtuoso ini file parameter.

If the test coverage file is specified the initial state of the accumulation is read from the coverage file if one exists. If the file does not exist then coverage starts from scratch.

The format of the file for store/restore of coverage data is:

```
<pl_stats>
  <proc name="xxx" calls="nn" file="ff" >
    <line no="xx" ctr="nn" /> ..
    <caller name="nnn" ct="nn" /> ..
  </proc>
  ...
</pl_stats>
```

An example of file:

```
<pl_stats>
  <proc name="DB.DBA.pop_get_command" calls="00000133" file="pop3_svr.sql" >
    <line no="000152" ctr="000133" />
    <line no="000153" ctr="000133" />
    <line no="000156" ctr="000133" />
    <caller name="DB.DBA.POP_IF_COMMAND" ct="000070" />
    <caller name="WS.WS.NN_SRV" ct="000063" />
  </proc>
</pl_stats>
```

For the purpose of making a Coverage report the format is extended. The lct attribute of the <proc> element contains a total number of lines for the procedure. The CDATA sections of the <line> element contain the excerpt of the line in question up to a maximum of 50 characters.

An example of the extended file format (made with cov_store ('ccc.xml', 1)) is:

```
<proc name="DB.DBA.pop_is_ok_" calls="00000034" file="pop3_svr.sql" lct="22" >
 <line no="000239" ctr="000034"><![CDATA[6    _idx := pop_atoi (num); ]]></line>
 <line no="000240" ctr="000034"><![CDATA[7    _all := length (_stat); ]]></line>
 <line no="000242" ctr="000034"><![CDATA[9    if ((_idx < 1) or (_idx > _all - 1)) ]]></line>
 <line no="000247" ctr="000034"><![CDATA[14    if (pop_is_deleted (_idx, _stat)) ]]></line>
 <line no="000253" ctr="000034"><![CDATA[20    return 1; ]]></line>
 <caller name="DB.DBA.POP_DELE" ct="000011" />
 <caller name="DB.DBA.POP_RETR" ct="000023" />
</proc>
```

The comment `--src xxxx:yyy` indicates the file xxx and line yyy. This comment will be added at the end line of each procedure when loading a file via isql or when generating SQL procedure constants for C code from sql files. These files and lines will be used for annotating the coverage report.

The function `cov_load()` is used to cumulatively load a test coverage file into a running system. Repeatedly calling this allows making a union of multiple separately obtained coverage files which will all show in the ultimate report.

The function `cov_store (in out_file varchar, in add_comments integer := 0)` is used to make an XML file for further XSL-T processing with `cov_report()` (see below) or to make a snapshot of current coverage statistics. The add_comments parameter is used to add a line info and count, usually it takes 1 for making the report, so internally it is used with add_comments equal to 0 to store the cumulative report in the TestCoverage file.

The function `cov_report (in file varchar, in outdir varchar)` makes the full coverage report based on the current state and writes it out.

The report consists of a summary file called profile.prof, containing execution counts and times for individual functions, sorted by self time as well as by time including called functions. For each distinct file mentioned in loaded procedures there is a file called <outdir>/<orgname>.sql.cov under the server's working directory. This file contains listings of all procedures from the file, annotated with line numbers at the start of each line. Each line with executable code will have an execution count. The line number field has six leading characters, the exec count is the next six characters, the line follows. The lines that are not executed are denoted with ## on place of exec count number.

Procedures that do not have source info associated are listed in name order in the file unnamed.sql.cov in the same directory.

An example of files generated by cov_report ('ccc.xml', 'cov/') are:

```
---->

>> begin <<<----
Lines: 806
TotalLines: 2741
Coverage: 29 %

[times called] [proc name]
    6250 : WS.WS.FINDPARAM
    --- code info
    [line in file] : [how many times executed] : [offset from beginning] [line excerpt]
       664 :   6250 : 5    if (pkey is null)
       665 :     ## : 6      pkey := '';
       666 :  12500 : 7    i := 0; l := length (params);
       667 :   6250 : 8    pkey := rtrim (pkey,': ');
```

```
   668 :   6250 : 9    while (i < l)
   670 :  35966 : 11        ret := http_request_header (vector (para
   671 :  35966 : 12        if (ret is not null)
   672 :   3014 : 13          return ret;
   673 :  32952 : 14        i := i + 1;
   675 :   3236 : 16    return '';

-- caller information
[time called] [from proc]
     6 : WS.WS.MOVE
     9 : WS.WS.COPY
   267 : WS.WS.UNLOCK

```

11.21.2. Coverage Functions

`cov_load()`

`cov_store()`

`cov_report()`

`pldbg_stats()`

`pldbg_stats_load()`

11.22. Row Level Security

Organizations often need to compartmentalize access to data. This may be implemented at the level of physically segregating systems, building specific application logic or within the database.

Physically disconnected systems can be troublesome in an increasingly integrated corporate IS environment. Building access rules into application logic, typically in a middle tier is possible and flexible but the protection runs the risk of being circumvented by direct access to the database, through business intelligence tools for example.

For these reasons some database level security enforcement is needed in most applications. SQL provides table and column level privileges which can be granted to users and roles. These do not address issues where one department's data should be accessible when another department's data should not. Such segregation within a table is usually done with views which hard-code selection criteria. The table itself will not be granted but views to specific ranges of rows will be granted to users.

This has the inconvenience of requiring administration of views and requiring applications to use different views for different end users.

Row level security or policy based security allows the SQL compiler to make choices according to which user is accessing any given table. Extra conditions will be introduced into a SQL statement at compile time in order to limit the user to a specific range of rows. This will apply equally to reading and modifying the table.

A policy is a SQL function that will be called by the SQL compiler each time a table having the policy is accessed in a user's query or stored procedure. The policy can return extra conditions which will be and'ed to the conditions in the query. After this is done, the new query is optimized and compiled. This mechanism makes it possible to transparently customize which information a user account sees without having to maintain a multiplicity of static views. This mechanism cannot be subverted by a user and will work no matter what application is used against the database.

Let us consider the example of a table of classified documents. To access a document, the user needs to have a record in a need-to-know table which forms a many-to-many between classifications and users. If the user is a member of the security_auditor role, all documents will be accessible. Users themselves may neither read nor update the need-to-know table.

```
create role staff;
create role security_auditor;
grant staff to security_auditor;
```

```
create table document (d_id varchar, d_changed datetime, d_author varchar, d_classification int, d_text l

create table document_access (da_classification int, da_user  varchar,
primary key (da_d_id, da_user));

grant all privileges on document to staff;
grant all privileges on document_access to security_auditor;

create procedure d_policy (in tb varchar, in op varchar)
{
  if (user_has_role (user, 'security_auditor')) return '';
   if (user_has_role (user, 'staff'))
    return 'exists (select 1 from document_access where da_user = user and da_classification = d_classifi
  return '1=2';
}

table_set_policy ('document', 'd_policy', 'IDUS');
```

These operations first define two roles, staff and security_auditor. The staff is not granted access to document_access, which is configured by security_auditor.

The policy function will, for each query accessing document, check if the user is a member of security_auditor. If so, there will be no extra conditions and all rows will appear. If the user is a member of staff, an extra condition checking the existence of a need to know is added. This will check that there is an entry in the document_access where the accessing user is granted access to the document's classification. If the user is neither member of staff nor of security_auditor, no rows will be returned since the always false condition of 1=2 is added.

Besides selects, the policy rule will apply to inserts, updates and deletes. This is caused by the 'IDUS' parameter to table_set_policy. Different policies may be defined for select, insert, update and delete. Most often these will be the same. Only one policy function is allowed per table and operation. In order to set a policy, one must either be the table's owner or dba. Policies do not apply to dba users.

We note that the need to know check accesses a table which is not granted to staff, even for reading. This is OK, since the predicate coming from the policy function has access rights of the owner of the policy function. The predicate is treated like a view body that were granted to the user making the query without requiring that component tables of the view were granted.

Since policies are processed at the level of SQL compilation, these will equally apply to local and remote tables.

Queries inside stored procedures are subject to policy. The user whose policies are consulted is the owner of the stored procedure. The policy conditions are fixed at the time of compiling the procedure. Reassigning a policy counts as a change to the table, causing recompilation of all concerned procedures, triggers and client statements.

Conclusions

Policies are an effective way of implementing a 'virtual private database,' providing for isolation between classes of users of the same application. The maintenance overhead is small compared to the trouble of maintaining views for each class of users. The table concerned remains one schema object with one name. Policies can be set and maintained without modification to applications and existing applications can be made to use policy based access control at no additional cost.

11.22.1. Row Level Security Functions

`table_set_policy()`

`table_drop_policy()`

11.23. Vectored Execution and Query Parallelization

Note: This feature only applies to Virtuoso 7.0 and later.

Vectored execution means executing queries or stored procedures simultaneously on multiple sets of parameters. Further, when a query contains a *JOIN* , a single invocation of the query will, with vectored execution, execute every consecutive *JOIN* step with multiple inputs. When every stage of a query's evaluation is performed on a large number of intermediate result rows at a time, two benefits are obtained:

1. The interpretation overhead disappears and
2. Locality of reference in

   JOINs

   can be better exploited.

For example, with a *JOIN* like:

```
SELECT  COUNT(*)
  FROM  part,
        lineitem
 WHERE  l_partkey = p_partkey
   AND     p_size < 23
OPTION  ( LOOP, ORDER );
```

the outermost *LOOP* of the query will look for parts with *p_size < 23* . The part keys of these are used as lookup keys for an index on *l_partkey* in *lineitem* . This index translates these values into values of the primary key, *l_orderkey* , *l_linenumber* , which is then used to get the data row with the price and discount. When each of these steps is done with tens of thousands of values at the same time, the SQL interpretation overhead is almost completely eliminated and locality can be exploited when accessing nearby rows. The chance of hitting nearby rows also increases when the size of the intermediate result batch increases.

11.23.1. Automatic Query Parallelization

If a query does not modify data, executes in *READ COMMITTED* isolation, and contains some form of aggregation or *ORDER BY* , it can be automatically parallelized. Parallelization typically splits the query's outermost *LOOP* into approximately equal size chunks, which are independently evaluated each on its own thread. The results are merged together when all are ready, and are combined in an aggregation or *ORDER BY* . This is entirely transparent to the user.

11.23.2. Configuration Parameters for Vectoring and Parallelization

The following virtuoso.ini [Parameters] section entries concern query parallelization and vectoring:

Note: These settings only apply to Virtuoso 7.0 and later.

- AsyncQueueMaxThreads :

  Sets the number of threads in a pool that is used for getting extra threads for running queries and for aq_request. Each running statement has at least one thread that is not allocated from this pool plus zero or more threads from this pool.

  Setting the pool size to the number of cores plus a few is a reasonable default. On platforms with core multithreading, one can count a core thread as a core for purposes of this parameter.

  If one expects to run many slow `aq_requests()` (see `async_queue()` , `aq_request()` , etc.), then the number of threads should be increased by the number of slow threads one expects.

  Slow threads are typically I/O bound threads used for web crawling or similar long-latency, low-CPU activity.

  Note: Only effective with Virtuoso 7.0 and later.
- ThreadsPerQuery :

  This is maximum number of threads that can be claimed from the thread pool by a single query. A value of one means that no query parallelization will take place, and all queries will run single threaded.

  The number of cores on the machine is a reasonable default if running large queries.

  Note that since every query is served by at least one thread, a single query taking all the extra threads will not prevent other queries from progressing.

  Note: Only effective with Virtuoso 7.0 and later.
- VectorSize This the number of simultaneous sets of query variable bindings processed at one time. The default is 10,000, which is good for most cases.

If we are evaluating the query:

```
SELECT COUNT (*)
FROM t1 a
NATURAL JOIN t2 b
WHERE a.row_no + 1 = b.row_no
OPTION (LOOP, ORDER)
```

with vector size of 10,000, then 10,000 rows of t1 a will be fetched first; 1 will be added to the 10,000 row_no values; and then the corresponding row of t1 b will be fetched for the 10,000 row_no of t1 a. This process will repeat until enough batches of t1 a have been fetched to come to its end.

Note: Only effective with Virtuoso 7.0 and later.

- AdjustVectorSize :

  Using a larger vector size when evaluating large queries with indexed random-access can yield up to a 3x speed-up relative to using the default vector size. However, always using a large vector size will prohibitively increase the overhead of running small queries. For this reason, there is the option to adaptively select the vector size. Set AdjustVectorSize = 1 to enable this feature. The SQL execution engine will increase the vector size when it sees an index lookup that does not get good locality, (e.g., after sorting the keys to look for, too few consecutive lookups fall on the same page). Having more keys to look up increases the chance that consecutive keys should be found on the same page, thus eliminating much of the index lookup cost.

  Note: Only effective with Virtuoso 7.0 and later.

- MaxVectorSize :

  When AdjustVectorSize is on, this setting gives the maximum vector size. The default is 1,000,000 and the largest allowed value is about 3,500,000.

  Note: Only effective with Virtuoso 7.0 and later.

Chapter 12. Database Event Hooks

Abstract

Virtuoso provides a number of hooks that enable you to traps events within the database such as startup, shutdown, connection, disconnection and SQL compilation events.

Virtuoso allows the dba to set hooks for various events, such as:

Startup
Shutdown
Client Connect
Client Disconnect
Compilation of a Dynamic SQL Statement

These events are intercepted by calling a SQL procedure if one is defined.

In the following we will examine each hook in the context of a simplified database security system. The system will record all logins and logouts and will enforce custom security rules on reading a specific application table.

12.1. Database Startup

`DB.DBA.DBEV_STARTUP()`

If defined, this is called after the server initialization, including roll forward of transaction logs, compilation of stored procedures, etc..., but before starting to listen for clients. Hence this is guaranteed to run before any clients connect or any HTTP messages are serviced.

The procedure will run in its own transaction, which will be automatically committed upon return, regardless of run time errors. Result sets are not allowed and return values are discarded. All custom Virtuoso Server Extensions (VSEs) will be defined when calling this procedure.

Example 12.1. Sample Startup Procedure Hook

```
create procedure DB.DBA.DBEV_STARTUP ()
{
  dbg_obj_print (' server started ');
}
```

12.2. Database Connections

`DB.DBA.DBEV_CONNECT()`

If defined, this hook is called for each successful ODBC or JDBC connection. The hook is only called after password and license checks have passed. The hook is called before the server acknowledges a successful connect and is therefore guaranteed to run before any other action by the connected client.

The function runs in its own transaction, which is automatically committed following successful return. Result sets may not be generated and return values are discarded. The connection_id () and user are defined in the function. SQL states signalled inside this hook will be sent to the client and will cause the connection to be closed server side.

Example 12.2. Simple Connection Logging

```
create table security_log (
  sl_user varchar,
  sl_logged_in datetime,
  sl_logged_out datetime,
  primary key (sl_user, sl_logged_in)
);

create procedure DB.DBA.DBEV_CONNECT ()
{
  dbg_obj_print (user, ' connected');
  if (user = 'NOGO')
    signal ('EAUTH', '  External Authorization Failed');
  insert into security_log (sl_user, sl_logged_in) values (user, curdatetime ());
  connection_set ('login_time', curdatetime ());
}
```

This function will print a message to the server's standard output, check if the username of the logged in user is NOGO and disconnect the user if so, This will thereafter insert a row into the security_log table and set the connection variable 'login_time' to be the current time. This information will be used at disconnect time to identify which entry to mark closed.

`DB.DBA.DBEV_DSN_LOGIN (inout dsn varchar, inout user_id varchar, inout pwd varchar, )`

If defined this function is executed just before Virtuoso makes connections to remote data sources. It can change all of it's inout parameters depending on it's logic.

Example 12.3. Remote Connection Hook

This examples contains a sample DBEV_DSN_LOGIN hook that will be called just before the Virtual Database connection to a datasource is made. The following parameters can be used in this function as demonstrated in this example:

dsn : the dsn to connect to

user_id : the user id used in connecting to the DSN

pwd : the password used in connecting to the DSN

```
create procedure "DB"."DBA"."DBEV_DSN_LOGIN"
(in dsn varchar,
 inout user_id varchar,
 inout pwd varchar)
{
  if (user_id = 'U1' and pwd = 'U1')
    {
      -- map U1 to U2
      dbg_obj_print ('mapping U1 to U2');
      user_id := 'U2';
      pwd := 'U2';
    }
   dbg_obj_print (dsn, user_id, pwd);
};
```

12.3. Database Logins

`DB.DBA.DBEV_LOGIN (inout user_name varchar, in digest varchar, in session_random varchar, )`

This function, if defined, will always be called by Virtuoso just before a client is authenticated against the Virtuoso Server. Three parameters are available for audit purposes or any other pre-processing purpose totally user definable.

1. *user_name:*

   IN : the user name from the login data

   OUT : the user name used by Virtuoso for this connection
2. *digest* : the password digest calculated by the client (or the password itself for older clients)
3. *session_random* : the random key used to calculate the digest

This hook can be used to control how Virtuoso proceeds with the client login by responding to 3 possible return values:

-1 - continue with normal verification

0 - reject the login

1 - allow the login (the user returned should be a valid Virtuoso local user name

Example 12.4. Sample Database Login Hook

```
create procedure "DB"."DBA"."DBEV_LOGIN" (
    inout user_name varchar,
    in digest varchar,
    in session_random varchar)
{
  -- the hook runs as DBA
  dbg_obj_print ('user=', user);

  -- and is compiled as DBA
  declare uid_cnt integer;
  uid_cnt := 0;
  select count (*) into uid_cnt from SYS_USERS where U_NAME = user_name;
  dbg_printf ('%ld local users found with this name', uid_cnt);

  if (user_name = 'masterdba')
    {
      -- 'masterdba' is a valid remotely defined user
      -- it's password is 'masterdbapwd'
      -- we're going to check it's password and then map it to dba

      declare md5_ctx any;
      declare my_digest varchar;
      declare pwd varchar;

      -- this is our assumption for the user's password
      -- this can come from an external source as well
      pwd := 'masterdbapwd';

      -- calculate the MD5 digest for checking the password that the client supplied.
      -- note that it uses the 'masterdba'/'masterdbapwd' to calculate it since we
      -- assume that these are the data the client supplied as user id and password
      --
      -- The way to calculate this is FIXED.
      -- The ONLY variables are the user id and the password

      -- START of the FIXED digest calculation sequence
      md5_ctx := md5_init();
      md5_ctx := md5_update(md5_ctx, session_random);
      md5_ctx := md5_update(md5_ctx, user_name);
      md5_ctx := md5_update(md5_ctx, pwd);
      -- the 0 parameter to the md5_final causes it to return the bytes
      -- instead of representing it as hexadecimal characters
      my_digest := md5_final (md5_ctx, 0);
      -- END of the FIXED digest calculation sequence

      -- now compare the calculated digest with the one supplied by the client
      -- note the OR here - some older clients MAY supply the password in plain text
      if (my_digest = digest or pwd = digest)
        {
          -- the match says that the client indeed supplied 'masterdbapwd' as a password
          dbg_obj_print ('masterdba validated');

          -- so map it to the local 'dba' user
          user_name := 'dba';
```

```
          -- and skip further verification
          return 1;
        }
      else
        {
          -- the password is not the one that we verify against
          dbg_obj_print ('masterdba pwd wrong');

          -- not allow the login at all
          return 0;
        }
    }
  else if (user_name = 'nobody')
    {
      -- the hook can signal :
      -- this is equal to returning -1, but has the additional benefit of an error message printed into t
      signal ('28000', 'we don''t map nobody');
    }
  else if (user_name = 'attacker')
    {
      -- that's a way to print a message to the log and reject the login
      log_message ('trying invalid user');
      return 0;
    }
  else
    {
      -- all local user_name/pwd are subject to normal verification
      dbg_obj_print (user_name);
      return -1;
    }
  -- note that not returning value causes the Virtuoso to print an appropriate message to the log
  -- and then continue with the normal verification
  -- same happens if the value returned is not 0, -1 or 1
};
```

`DB.DBA.USER_FIND (in name varchar, )`

This is a user-defined PL function hook which, if it exists, will be executed before doing the SQL/ODBC login. In this hook the user can find a user account from some other server and register it in the local database. Or, this can be used to perform some pre-login actions. It is similar to the DBEV_LOGIN, but it does not change any account validation rule, it is purely for pre-processing.

12.4. Database Disconnections

`DB.DBA.DBEV_DISCONNECT()`

If defined, this procedure is called after a connection has been found to be disconnected, either as a result of the client process disconnecting, the client process terminating or the server deciding to disconnect, see disconnect_user() . This will also be called if the DBEV_CONNECT hook signals an error, leading to the connection being closed during the connect sequence.

All activity on behalf of the disconnecting client is terminated by the time this function is called. This function runs in its own transaction. Result sets are prohibited, return values discarded and errors are logged in the error log file but not otherwise processed. The transaction is committed regardless of errors. The user and connection_id and any connection variables are defined during this hook.

Example 12.5. Disconnect Interception

```
create procedure DB.DBA.DBEV_DISCONNECT ()
{
  declare ctime datetime;
  dbg_obj_print (user, ' disconnected');
  ctime := connection_get ('login_time');
  update security_log set sl_logged_out = now () where
    sl_user = user and sl_logged_in = ctime;
  if (row_count () = 0)
    signal ('ELOGO', 'Logout by user with no login record.  This occurs when DBEV_CONNECT denied permissi
```

```
}
```

This function updates the row created by the connect hook to set the logout time.

12.5. Database Shutdown

`DB.DBA.DBEV_SHUTDOWN()`

If defined, this function is called when shutting down the server, following disconnection of all clients and making a checkpoint. When a disconnect occurs as a result of server shutdown the DBEV_DISCONNECT hook is not called and this function is expected to perform any logout processing. The rationale is that all disconnect hooks would be called at the same time, creating likely deadlocks, resource contention and there could be no guarantee of time consumed by them or of even whether they would terminate at all.

The shutdown will do a checkpoint before calling this hook. This checkpoint will terminate all transactions with a deadlock state. If transactions contain automatic retries, etc..., we cannot guarantee that all activity would have terminated when this hook starts. However, the hook function can try

```
txn_killall (6);
rollback work;
```

to signal an error on all other transactions to prompt them to terminate. Again, this is not a sure-fire termination since this could be handled by procedures.

When this hook returns the server commits the transaction in which this was running and exits regardless of any lingering activity. There is no hard time limit for this function. Killing the process during this function has no specific ill effect, besides losing uncommitted work by said function.

Result sets are prohibited, return values are discarded, errors are logged but not otherwise processed.

Example 12.6. The Shutdown Hook

```
create procedure DB.DBA.DBEV_SHUTDOWN ()
{
  dbg_obj_print (' server shut down.');
  update security_log set sl_logged_out = now () where sl_logged_out is null;
}
```

This just marks all open connections to be disconnected at the current time.

12.6. SQL Statement Preparation

`DB.DBA.DBEV_PREPARE(`*`inout tree any`*` )`

```
DB.DBA.DBEV_PREPARE (inout tree any)
```

If defined, this function is called after parsing any dynamic SQL statements by any users. The parse tree will be a syntactically correct SQL parse tree. The user and connection variables are defined. The hook should not produce a result set and any return values are discarded. The function runs in the transaction which is current on the connection and the transaction is not automatically committed, so that the hook does not modify application transaction boundaries.

The tree may be modified by replacing it with any other correct parse tree or destructively splicing it. The tree is a regular SQL heterogeneous array. If the tree is modified incorrectly, it is probable that the server will crash.

The parse tree manipulation is best written in C as a Virtuoso Server Extension using the supplied SQL parse tree typedef and constants.

If an error occurs inside this hook the error is simply ignored and the unmodified parse tree is used. To signal an error to a user it is possible to change the parse tree into a call to the signal SQL function.

Example 12.7. SQL Prepare Hook

```
CREATE TABLE REPORT (
  R_AUTHOR VARCHAR,
  R_ID INTEGER IDENTITY,
  R_CLASS INTEGER,
  R_TEXT LONG VARCHAR,
  PRIMARY KEY (R_ID)
);

CREATE TABLE NEED_TO_KNOW (
  NK_CLASS INTEGER,
  NK_USER INTEGER,
  PRIMARY KEY (NK_CLASS, NK_USER)
);

grant select on REPORT to public;

create procedure DB.DBA.DBEV_PREPARE (inout tree any)
{
  declare uid integer;
  uid := (select U_ID from SYS_USERS where U_NAME = user);
  need_to_know (uid, tree);
  dbg_obj_print ('compiled by ', user, ': ', tree);
}
```

This example has a table of variously secret reports, each having a class or compartment and different users having a need to know about a certain collection of compartments. The need_to_know table references U_ID in SYS_USERS and R_CLASS in REPORT. Each select referencing REPORT is modified by the `need_to_know` VSE in order to add a check for the need to know.

For example,

```
select * from REPORT
```

becomes

```
select * from REPORT
  where exists (select 1 from NEED_TO_KNOW
    where NK_CLASS = R_CLASS and NK_USER = <user>)
```

where <user> is the id of the user preparing the query.

As a result, all queries referencing the REPORT table, no matter how they are phrased, will not access rows for which the user does not have a need to know. Note that the REPORT table can be granted to public, unauthorized users will just get an empty result. Further, note that the NEED_TO_KNOW table is not granted to anyone, hence the user does not even need to know the extent of his need to know let alone that of any other user. The expansion of the need to know test inserts the table reference as in a view expansion, where it's privileges are not those of the user but of the view owner, or in this case the procedure owner, which is always dba.

12.7. SQL Parse Tree

The SQL parse tree is composed of DV_ARRAY_OF_POINTER boxes. Other types of boxes may occur as leaves, where they are interpreted as literals. All nodes' first element (index 0) is the type of the node, one of the constants in sqlparext.h.

The nodes' various fields can be accessed through the data members of the sql_tree_t union. Most data members are pointers to the same type. Sometimes they are double pointers, denoting a variable length array of pointers to the struct. The caddr_t type is used to denote a terminal, like a string or other constant. The types are only for declarative value, the entire structure is a self describing, run time typed tree of boxes.

The correspondence of the tree to the SQL syntax is documented by the yacc grammar supplied as appendix.

We will next examine the need to know example:

```
ST *
nk_tree_and (ST* left, ST * right)
{
  if (left && right)
    return ((ST*) list (4, BOP_AND, left, right, NULL));
  if (left)
    return left;
  return right;
}
```

This function adds anAND operation between 2 sub trees. If either is NULL, the non-null one is returned. The list function is used as a universal constructor of the parse tree, where the first argument is the count of arguments to follow.

The above could have been written as follows without list:

```
ST * r = (ST*) dk_alloc_box (4 * sizeof (caddr_t), DV_ARRAY_OF_POINTER);
r->type = BOP_AND;
r->_.bin_exp.left = left;
r->_.bin_exp.right = right;
r->_.bin_exp.more = NULL;
```

We see that the list notation is more concise.

```
void
nk_test_add (ST * outer_texp, char * corr_name, int uid)
{
  /* add a exists (select 1 from need_to_know where nk_class = <corr_name>.r_class) */
  ST * sel, * exists, * texp, **from;
  ST * where = (ST*) list (4, BOP_EQ, list (3, COL_DOTTED, NULL, box_string ("NK_CLASS")),
                           list (3, COL_DOTTED, box_string (corr_name), box_string ("R_CLASS")), NULL);
  where = nk_tree_and (where, listst (4, BOP_EQ, list (3, COL_DOTTED, NULL, box_string ("NK_USER")), box_
  from = (ST**)
    list (1, list (3, TABLE_REF,
                   list (5, TABLE_DOTTED,
                         box_string ("DB.DBA.NEED_TO_KNOW"),
                         NULL, box_num (0), box_num (0)),
                   NULL));
  texp = listst (7, TABLE_EXP, from,
                 where, NULL, NULL, NULL, -1);
  sel = listst (5, SELECT_STMT, NULL, list (1, box_num (1)), NULL, texp);
  exists = (ST*) list (5, EXISTS_PRED, NULL, sel, NULL, NULL);
  outer_texp->_.table_exp.where = nk_tree_and (outer_texp->_.table_exp.where, exists);
}
```

This function takes the table expression referencing the REPORT table and the correlation name used for the table and the user id of the querying user. It adds the existence test for the need to know. The logic is self evident when examined in the context of the yacc grammar. Note that the table in the FROM of the sub query is a TABLE_REF node with a TABLE_DOTTED node, which finally contains the table and correlation names. Note that all strings must be allocated as string boxes. This is because the tree may only reference other boxes. Note that all numbers except for the types of the nodes are boxed with box_num. This will make sure that numbers and pointers are always distinguishable. The node types are distinguishable by definition due to their small absolute value.

```
caddr_t
bif_need_to_know (caddr_t * qst, caddr_t * err_ret, state_slot_t ** args)
{
  unsigned inx;
  caddr_t uid = (caddr_t) bif_long_arg (qst, args, 0, "need_to_know");
  ST * tree = (ST*) bif_array_arg (qst, args, 1, "need_to_know");
  if (ST_P (tree, SELECT_STMT))
    {
      ST * texp = tree->_.select_stmt.table_exp;
      if (!texp)
        return 0; /* select w/o a from */
      for (inx = 0; inx < BOX_ELEMENTS (texp->_.table_exp.from); inx++)
        {
          ST * tref = texp->_.table_exp.from[inx];
          if (ST_P (tref, TABLE_REF))
            tref = tref->_.table_ref.table;
          if (ST_P (tref, TABLE_DOTTED))
            {
```

```
                char * corr_name;
                if (tref->_.table.prefix)
                  corr_name = tref->_.table.prefix;
                else
                  corr_name = tref->_.table.name;
                if (strstr (tref->_.table.name, "REPORT"))
                  nk_test_add (texp, corr_name, (int)uid);
              }
          }
      }
    return 0;
  }
```

This is the top level need to know function. It first checks to see that the statement is a select, that it has a FROM clause (table expression). For each table in the FROM which has REPORT as part of its name the function adds an existence test to check the user's need to know. Note that the correlation name is taken from the table and that the table name is used in the absence of a correlation name to disambiguate the reference. Note that the table_exp.from is of type ST **, meaning a variable length array of boxes. Note that BOX_ELEMENTS returns the length in pointer-size units.

Note that in this example the tree is spliced in place, only adding nodes. There is no need to free data or to modify the top node.

12.7.1. Notes on Special Features of the Parse Tree

The parse tree structure has a 1 to 1 correspondence with the yacc grammar. The members of the union in sql_tree_t are mostly named after the syntactic element and the constant that identifies them. There are however some points worth noting:

Literals - All boxes whose tag is not DV_ARRAY_OF_POINTER are considered literals and may appear in all places where a literal is allowed.

Identifier Case - The case conversion of identifiers is controlled by the CaseMode ini file setting. When introducing a constant name referencing a VSE, one should use sqlp_box_id_upcase to get the right case for all modes.

The identifiers, once in the tree, are compared case sensitively in all modes case modes except 2.

Hook functions should use the appropriate comparison functions for the desired case sensitivity.

When generating references to names the case should be correct as defined by the case mode.

12.7.2. SQL Security and Parse Trees

When compiling table access the access rights granted on the table are checked against the user and group marked on the table reference (TABLE_DOTTED) parse tree node. When a user writes a table reference the user id and group of the user are marked in the parse tree and these are compared against the grants in effect.

When a table reference comes from a view the reference is annotated with the view owner's user id and group. Hence a view may introduce references that would not otherwise be granted to a user.

This is used in the need to know example, marking the group and user of the reference to NEED_TO_KNOW to be 0, meaning dba.

There are no other security related features in the parse tree. Procedure security is resolved exclusively at run time.

12.7.3. Debugging with Parse Trees

It is extremely easy to make errors when manipulating parse trees in code. A useful technique will be to print out the tree before and after the operation. This can be conveniently done in the hook function with dbg_obj_print, as shown in the example.

Once the modified tree is returned to the SQL compilation, the system checks for it for absence of cycles, so that no two branches are the same. There is an assertion failure if this happens. Otherwise the tree is not checked. Hence a malformed tree will in all likelihood crash the server during the compilation.

12.8. WebDAV Logins

```
DB.DBA.DBEV_DAV_LOGIN (inout user_name varchar, in password varchar, in http_auth any,
)
```

This function, if defined, will always be called by Virtuoso just before a HTTP client is authenticated against the WebDAV Server. Three parameters are available for audit purposes or any other pre-processing purpose totally user definable.

1. *user_name:*

   IN : the user name from the login data

   OUT : the user name used by WebDAV server for this request
2. *password* : the encrypted password that corresponding to the `user_name`
3. *http_auth* : HTTP authentication information (see below)

The data structure of the `http_auth` is an array containing name/value pairs as described below.

For HTTP Basic authentication:

method - HTTP method : GET/POST/PUT etc.
authtype - string 'Basic'
username - the same as `user_name` parameter
pass - the password (in case of basic authentication only)

For HTTP Digest authentication:

method - HTTP method : GET/POST/PUT etc.
authtype - string 'Digest'
username - the same as `user_name` parameter
realm - authentication realm
qop - Indicates what "quality of protection" the client has applied to the message
algorithm - hashing algorithm used to create the checksum or digest
uri - the URI from Request-URI of the Request-Line
nonce - data string which may be uniquely generated
nc - The nc-value is the hexadecimal count of the number of requests (including the current request)
cnonce - The cnonce-value is an opaque quoted string value provided by the client
opaque - string value provided by the server and returned by the client unchanged
response - string containing password hash as described in RFC 2617

An example of the `http_auth` value:

```
vector ('method', 'GET', 'authtype', 'basic', 'username', 'MyUser', 'pass', 'My!Secret')
```

This hook can be used to control how Virtuoso proceeds with the WebDAV client login by responding to 3 possible return values:

-1 - continue with normal verification
0 - reject the login
1 - allow the login (the user returned should be a valid Virtuoso local user name)

Example 12.8. Sample WebDAV Login Hook

```
create procedure
DB.DBA.DBEV_DAV_LOGIN (inout user_name varchar, in pwd any, in auth any)
{
  declare result any;

  WHENEVER SQLSTATE '28000' GOTO validation_failure;

  -- All accounts that are not WebDAV admin are going here
  if (lcase(user_name) <> 'dav')
    {
      declare pass any;

      -- use password from request if basic HTTP authentication is used
      if (get_keyword ('authtype', auth) = 'basic')
        pass := get_keyword ('pass', auth);
```

```
      else -- or use the password from database if digest
        pass := pwd_magic_calc (user_name, pwd, 1);

      -- set appropriate LDAP protocol version
      connection_set ('LDAP_VERSION', 2);
      commit work;
      result := LDAP_SEARCH('ldap://mail2.openlinksw.com:389',
                0, 'ou=Accounts, o=OpenLink Software, c=US', sprintf ('(uid=%s)', user_name),
                sprintf('uid=%s, ou=Accounts, o=OpenLink Software, c=US', user_name),
                pass);
      return 1;
    }
  -- normal authentication for WebDAV admin
  return -1;

  -- all accounts that are not authenticated by LDAP are rejected
validation_failure:
  return 0;
};
```

12.9. Associating Auxiliary Data With A Connection

The following functions allow you to set and retrieve connection variables:

- connection_id()
- connection_set()
- connection_get()

Chapter 13. Data Replication, Synchronization and Transformation Services

Abstract

This chapter describes how to replicate data between Virtuoso and non-Virtuoso servers.

The material in this chapter covers the programmatic means of performing these operations. You can also use the graphical interface to do replication and synchronization. This is covered in the Replication & Synchronization section of the Visual Server Administration Interface chapter.

13.1. Introduction

Virtuoso provides several replication methods:

13.1.1. Snapshot replication

Virtuoso provides the following flavors of snapshot replication:

Non-incremental snapshot replicationNon-incremental snapshot replication is useful when the data is changed infrequently or when data is modified in large portions at a time.

Incremental snapshot replication Incremental snapshot replication is useful when the data is changed frequently and implements incremental updates using a snapshot log.

Bi-directional snapshot replication Bi-directional snapshot replication allows data to be modified on both publisher and subscribers. This is useful read-write access to the replicas is needed.

Note:

Snapshot replication can be used in heterogeneous environments to set up replication between non-Virtuoso databases.

13.1.2. Transactional replication

Transactional replication allows subscribers to receive data in near-real time. ACID properties of transactions are maintained in transactional replication as well. Virtuoso implements the following flavors of transactional replication:

Ordinary transactional replicationOrdinary transactional replication flavor implements one-way data replication and is useful when data can be modified on only one server with other servers participating in replication providing read-only data access.

Bi-directional transactional replication Bi-directional transactional replication is useful when there is a requirement to allow data updates on multiple servers.

13.2. Snapshot Replication

13.2.1. Non incremental snapshot replication

The Virtuoso Server periodically evaluates a query and inserts the result into a table, replacing the content. The source and target can be anywhere but typically will be on different databases of which at least one is remote.

This makes a two party distributed transaction. Only one of the transaction branches is writing, hence this goes with a one phase commit.

Note:

This can be used to replicate between two non-Virtuoso databases.

The prerequisite of this mode of replication is that all tables exist. The schema is never replicated.

13.2.2. Incremental snapshot replication

A table can be replicated from a generic, possibly non-Virtuoso source in an incremental fashion if the data source meets certain criteria:

The data should come from a single table.

The source table should have an explicit primary key.

There source query should have the form

```
SELECT fields FROM source_table WHERE scalar_conditions
```

A snapshot log on the source table should exist.

There should be insert, delete and update triggers on the source table to update the snapshot log.

The incremental update is done in the following way:

All the changed records with a snaptime greater or equal from REPL_START_TIME(SN_LAST_TS) are processed. If the record to insert already exists, then it is updated. If the record to update does not exist in the destination table, then it is inserted. This contributes for conflict resolving.

13.2.3. Command reference

CREATE SNAPSHOT LOG FOR source_table

```
CREATE SNAPSHOT LOG FOR source_table
```

```
repl_create_snapshot_log(in source_table varchar)
```

Creates a snapshot log of a native (non VDB) table and the appropriate log update triggers.

Note that when replicating data from a remote Virtuoso a snapshot log table can be created on the remote virtuoso and then the source and log tables can be attached into the local Virtuoso. However the snapshot log table and the update triggers should be created manually on a non-Virtuoso data source.

Examples (based on Virtuoso demo database):

```
create snapshot log for Orders;
```

DROP SNAPSHOT LOG FOR source_table

```
DROP SNAPSHOT LOG FOR source_table

repl_drop_snapshot_log(in source_table varchar)
```

Drops a snapshot log of a table and the log update triggers.

This results in 4 SQL commands :

```
drop trigger xxx_I_log;
drop trigger xxx_U_log;
drop trigger xxx_D_log;
drop table RLOG_xxx;
```

where xxx is the source table name (fully qualified - DB.DBA.Orders becomes DB_DBA_Orders).

Examples (based on Virtuoso demo database):

```
drop snapshot log for Orders;
```

PURGE SNAPSHOT LOG FOR source_table

```
PURGE SNAPSHOT LOG FOR source_table

repl_purge_snapshot_log(in source_table varchar)
```

There can be old snapshot log rows which have been replayed in all the snapshots of a given source table. These rows are no longer needed and can be purged from the snapshot log for faster operation.

This command checks if there are any rows in SYS_REPLICATION referring to that source table and if there are, then it deletes all the rows in the log table with SNAPTIME earlier then REPL_START_TIME(MIN(SN_LAST_TS)).

If there are no rows in SYS_SNAPSHOT it assumes that the log is used for "pull" replication and does not do anything.

Examples (based on Virtuoso demo database):

```
purge snapshot log for Orders;
```

CREATE NONINCREMENTAL SNAPSHOT

```
CREATE NONINCREMENTAL SNAPSHOT dest_table as 'query_def'

repl_create_snapshot(in query_def varchar, in dest_table varchar)
```

Creates a non-incremental snapshot log of the data returned by the query query_def.

The server first checks for the existence of a table with the same name. If it does not exist, then a table with a layout to accommodate the resultset produced by query_def is created.

Then a entry containing query_def and tablename is added to SYS_SNAPSHOT and the destination table is filled in with an insert into tablename query_def.

Examples (based on Virtuoso demo database):

```
create nonincremental snapshot sub_orders as
                'select * from Orders where OrderID < 5'
```

CREATE INCREMENTAL SNAPSHOT

```
CREATE SNAPSHOT dest_table FROM source_table [ 'source_column_list' ]
                [ WHERE 'condition' ]

repl_create_inc_snapshot(
    in source_column_list varchar,
    in source_table varchar,
    in condition varchar,
    in dest_table varchar)
```

Creates a incremental snapshot log using source query like that :

```
SELECT source_table_pk_cols, source_column_list FROM source_table WHERE condition
```

If the dest table already exists, then it's column count is checked to be greater than the primary key parts count of the source table.

If the source_column_list is omitted, then the destination table is created to have the same columns as the source table.

Examples (based on Virtuoso demo database):

```
CREATE SNAPSHOT sub_orders FROM Orders WHERE 'OrderID < 5'
```

UPDATE SNAPSHOT

```
UPDATE SNAPSHOT snapshot_table_name [ AS NONINCREMENTAL ]

repl_refresh_inc_snapshot(
    in snapshot_table_name varchar)

repl_refresh_noninc_snapshot(
    in snapshot_table_name varchar)
```

Without the optional argument updates the snapshot according to it's type. If an incremental snapshot needs to be updated as a nonincremental, then the full form should be used.

Examples (based on Virtuoso demo database):

```
UPDATE SNAPSHOT sub_orders
```

DROP SNAPSHOT

```
DROP SNAPSHOT snapshot_table_name [ WITH DELETE ]

repl_drop_snapshot(
    in snapshot_table_name varchar,
    in delete integer)
```

Removes a snapshot definition from SYS_SNAPSHOT and optionally drops the snapshot destination table.

Examples (based on Virtuoso demo database):

```
DROP SNAPSHOT sub_orders WITH DELETE
```

13.2.4. Bi-Directional Snapshot Replication

Bi-directional snapshot replication allows you to set up snapshot replication between multiple servers where updates can be performed on all servers. Bidirectional snapshot replication uses the publisher-subscriber model where each table or DAV collection has only one publisher and when an update is performed on subscriber it goes to publisher first, and then to all other

subscribers. Conflict resolution may need to take place on the publisher when data coming from a subscriber is processed. Bi-directional snapshot replication uses snapshot logs on publisher and subscribers to track changes in published table and its replicas.

It is assumed that all tables published using bi-directional snapshot replication have primary keys columns that are never modified.

To perform conflict resolution a ROWGUID column is added to every published table. This column should never be modified manually. All INSERT statements should specify exact column-select-lists that do not include the ROWGUID column. Likewise the ROWGUID column should never feature in any UPDATE statements.

Each server participating in bi-directional snapshot replication must have unique name (replication name). For Virtuoso servers replication name is assigned to the server in its virtuoso.ini file in the DBName setting. For other RDBMS servers replication name is the name of instance or the name of database. Replication name of remote server can be obtained using `REPL_SERVER_NAME()` (after this server is defined, see below).

`REPL_CREATE_SNAPSHOT_PUB()` function should be used to create bi-directional snapshot publication.

To create subscription for the publication, replication subscriber server should be defined first using `REPL_SNP_SERVER()` function. The name of the server can be obtained later using `REPL_SERVER_NAME()` function. After this `REPL_CREATE_SNAPSHOT_SUB()` function should be used to create a subscription (and create replicated table on subscriber if table replication takes place).

To load initial data on subscriber `REPL_INIT_SNAPSHOT()` should be used after subscription is created. Loading initial data can take some time so `REPL_INIT_SNAPSHOT()` performs commits after every 100 rows are copied from source table to the table on subscriber to prevent running out of transaction log or deadlocks. It is possible to specify an alternative value for number of rows per transaction (last parameter of `REPL_INIT_SNAPSHOT()` function). In DAV case commits are performed per copied resource.

`REPL_UPDATE_SNAPSHOT()` should be called periodically after initial data is loaded on subscriber to sync published items (tables or DAV collections) on publisher and subscribers. This function reads snapshot logs attached from subscribers and replays them with possible conflict resolution. After all snapshot logs from subscribers are processed an updating procedure reads snapshot log on publisher and replays it on all subscribers.

Note:
Please note that all operations in bi-directional snapshot replication (publication, subscription, doing initial copy, syncing) should be performed on publisher.

Example 13.1. Creating bi-directional snapshot publication

This example demonstrates creating bi-directional snapshot publication of table 'Demo.demo.Shippers'.

```
SQL> REPL_CREATE_SNAPSHOT_PUB ('Demo.demo.Shippers', 2);
```

Example 13.2. Creating bi-directional snapshot subscription

This example demonstrates creating bi-directional snapshot subscription for table 'Demo.demo.Shippers' and loading initial data on subscriber with DSN 'localhost:1121'.

```
SQL> REPL_SNP_SERVER ('localhost:1121', 'dba', 'dba');
SQL> REPL_CREATE_SNAPSHOT_SUB (REPL_SERVER_NAME ('localhost:1121'), 'Demo.demo.Shippers', 2);
SQL> REPL_INIT_SNAPSHOT (REPL_SERVER_NAME ('localhost:1121'), 'Demo.demo.Shippers', 2);
```

Example 13.3. Syncing bi-directional snapshot publication

This example demonstrates syncing bi-directional snapshot publication of table 'Demo.demo.Shippers'.

```
SQL> REPL_UPDATE_SNAPSHOT ('Demo.demo.Shippers', 2);
```

See Also:

The following functions are used for creating, dropping and updating publications and subscriptions to them:

`REPL_CREATE_SNAPSHOT_SUB()`

`REPL_CREATE_SNAPSHOT_PUB()`

`REPL_DROP_SNAPSHOT_SUB()`

`REPL_DROP_SNAPSHOT_PUB()`

`REPL_INIT_SNAPSHOT()`

`REPL_UPDATE_SNAPSHOT()`

`REPL_SNP_SERVER()`

`REPL_SERVER_NAME()`

Conflict Resolution

Since every table can have only one publisher, conflicts can only occur on the publisher when modifications from a subscriber are attempted. When DML operations originating on a subscriber are being replayed on the publisher, three types of conflicts can arise:

1. **uniqueness conflict (insert conflict).** occurs when the row with some primary key <PK> already exists in publisher's table.
2. **update conflict.** occurs when UPDATE modifies a row which has already been modified on publisher (by the publisher or another subscriber)
3. **delete conflict.** occurs when DELETE deletes a row that does not exist on publisher anymore.

Delete conflicts when UPDATE modifies a row that does not exist on publisher can't be detected in snapshot replication case.

Every table has a number of conflict resolvers which are used for conflict resolution which are enlisted in the `DB.DBA.SYS_SNAPSHOT_CR` system table. Each conflict resolver has a type, one of ('I', 'U', or 'D'), and an order. Conflict resolvers are applied in ascending order.

The conflict resolver is a Virtuoso/PL procedure that receives a conflicting row from a subscriber and some other arguments. The conflict resolver can modify the row, which is passed as an 'inout' argument. The conflict resolver should return an integer value, which will be used for conflict resolution.

Conflict resolvers of different types have different signatures:

'I' - Insert conflict resolvers (<ALLCOLS>, inout _origin varchar)

'U' - Update conflict resolvers (<ALLCOLS>, inout _origin varchar)

'D' - Deletion conflict resolvers (<PK>, inout _origin varchar)

where

<ALLCOLS> are the new values of all columns (including the ROWGUID column), <PK> are the values of primary key columns, and _origin is transaction originator.

Conflict resolvers can return the following integer values; The conflict resolver types concerned for each are listed in parentheses:

- **0 - un-decide (I, U, D).** next conflict resolver will be fired.
- **1 - subscriber wins (I, U, D).** DML operation will be applied with <ALLCOLS> All the subscribers except originator will receive modifications (originator already has them).
- **2 - subscriber wins, change origin (I, U).** DML operation will be applied with <ALLCOLS> and origin of transaction will be changed to publisher's server name. All the subscribers (including originator) will receive modifications. This return value is useful when conflict resolver changed some of the columns of the row that were passed in. Although all

parameters of conflict resolver are inout only changing of <ALLCOLS> (non-PK columns) parameters makes sense.

- **3 - publisher wins (U).** DML operation will be applied with <ALLCOLS> taken from publisher's table. All the subscribers will receive modifications.
- **4 - reserved.**
- **5 - ignore (D).** DML operation is ignored.

Conflict resolution stops when some conflict resolver returns a non-zero value meaning that it has made a decision.

Example 13.4. Conflict Resolution

Suppose we have the following table:

```
create table items(
  item_id integer primary key,

  name varchar,
  price decimal
);
```

"Publisher wins" 'I' conflict resolver will look like:

```
create procedure items_cr(
    inout _item_id integer,
    inout _name varchar,
    inout _price decimal,
    inout _origin varchar)
  returns integer
{
  return 3;
}
```

The conflict resolver that will make a decision based on the minimal price column will look like:

```
create procedure items_cr(
    inout _item_id integer,
    inout _name varchar,
    inout _price decimal,
    inout _rowguid varchar,
    inout _origin varchar)
  returns integer
{
  declare p decimal;
  -- get current price value
  select price into p from items where item_id = _item_id;
  if (p < _price)
    return 3;                   -- publisher wins
  else if (p > _price)
    return 1;                   -- subscriber wins
  return 0;                     -- can't decide
}
```

The conflict resolver that will change the price to the minimal value will look like:

```
create procedure items_cr(
    inout _item_id integer,
    inout _name varchar,
    inout _price decimal,
    inout _rowguid varchar,
    inout _origin varchar)
  returns integer
{
  declare p decimal;
  -- get current price value
  select price into p from items where item_id = _item_id;
  if (p < _price)
    {
      _price := p;
      return 2;                 -- publisher wins, change origin
    }
```

```
  return 1;                     -- subscriber wins
}
```

Conflict resolution occurs differently for each kind of DML operation:

- **INSERT.** When INSERT of some row with primary key <PK> is replayed, the row in the publisher's table with such <PK> is looked-up. If the row does not exist then there is no conflict, conflict resolution stops and the INSERT is replayed. If the row exists then we have a "uniqueness conflict". In this case 'I' conflict resolvers are fired-up. If none of the 'I' conflict resolvers were able to make a decision (return non-zero value) the default action is 'publisher wins'.
- **UPDATE.** When there is an UPDATE of some row with primary key <PK> is replayed, the row (and its ROWGUID) in publisher's table with such <PK> is looked-up. If the row does not exist then we have a "delete conflict", 'D' conflict resolvers are fired up. If none of the 'D' conflict resolvers were able to make a decision the default action will be to 'ignore'. If the row exists in the publisher's table and its ROWGUID is the same as that from the subscriber then there is no conflict. Conflict resolution stops and the UPDATE is replayed. If the row exists and its ROWGUID differs from the one that came from subscriber then we have an "update conflict". In this case the 'U' conflict resolvers are fired-up. If none of the 'U' conflict resolvers were able to make a decision (return non-zero value) the default action will be 'publisher wins'.
- **DELETE.** When DELETE operation of some row with primary key <PK> is replayed, the row in the publisher's table with such <PK> is looked-up. If the row does not exist or if the row exists but its ROWGUID differs from the one that came from subscriber then we have "delete conflict". The 'D' conflict resolvers are fired-up. If none of the 'D' conflict resolvers were able to make a decision then the default action will be taken to 'ignore'. Otherwise it is assumed that there is no conflict and DELETE statement is replayed.

Conflict Resolution in WebDAV

Conflict resolvers in DAV are found based on the collection. The closest collection that specifies resolvers will be the one providing the resolver set. Resolvers from any enclosing collection will not be invoked.

There is special subcollection in each replicated collection named '_SYS_REPL_BACKUP'. This subcollection is never replicated and is used to store backup copies of resources that lose conflict resolution.

If a resource is locked during an update it will be stored in temporary location. Conflict resolution will take place after the lock is released. If the update was performed on the publisher then no conflict resolution will be performed on the subscribers and the resource from temporary location will simply replace an existing resource after the lock is released.

Default conflict resolution is 'publisher wins'.

Delete conflicts are not handled when replicating DAV because updates are the same as inserts -- if the resource that was updated does not exist it will be created. INSERT or uniqueness conflict for the same reasons.

Subcollections are not considered in conflict resolution. Subcollections are always created as needed during an update. This means that if a resource is updated locally but collection that holds this resource does not exist on remote peer it will be created.

Automatically Generated Conflict Resolvers

Simple table conflict resolvers can be generated automatically by calling the `REPL_ADD_SNAPSHOT_CR()` function. DAV conflict resolvers be generated by calling `REPL_ADD_DAV_CR()` function.

See Also:

`REPL_ADD_DAV_CR()`

`REPL_ADD_SNAPSHOT_CR()`

The generated procedures can be modified afterwards. In particular it is possible to change the notification e-mail address by setting the _notify_email parameter, and the notification text by setting the _notify_text parameter.

The default behaviour for generated procedures is 'pub_wins', making a backup and notifying the owner by e-mail.

13.2.5. Registry variables

1. *snp_repl_tolerance_offset* (default 15) In incremental and bi-directional snapshot time stamp of last replayed snapshot log entry (LAST_TS) is kept in system tables. LAST_TS is used to determine the starting point of the next update. This value can't be used as is for the following reasons:

   Local time may be adjusted occasionally on the servers which participate in replication.

   Virtuoso snapshot replication triggers use `now()` function to get snapshot log entry time stamp. If transaction is started before updating snapshot log and ended after updating snapshot log is finished, data modifications made in this transaction will be missed.

   In order to resolve the issues mentioned above Virtuoso reads snapshot logs starting from LAST_TS minus some tolerance offset. The value of tolerance offset (in minutes) is kept in "snp_repl_tolerance_offset" registry variable. For the reasons mentioned above tolerance offset should be longer than length of any transaction which modifies published tables.
2. *snp_repl_purge_offset* (default 30) In order to prevent snapshot log entries to be replayed more than once Virtuoso keeps log of replayed snapshot log entries (rplog). Rplog entries need to be purged periodically. Virtuoso automatically schedules rplog purger when snapshot log for some table is created. All the records in rplog with time stamp less than MIN(LAST_TS) minus some offset are purged. The value of purge offset (in minutes) is kept in "snp_repl_purge_offset" registry variable. Normally, purge offset should be greater than tolerance offset.

13.2.6. Heterogeneous snapshot replication

Virtuoso allows incremental and bi-directional snapshot replication flavors to be used with non-Virtuoso databases.

The following databases are supported in incremental snapshot replication:

SQL Server 2000 and later
Oracle 8i and later
IBM DB2 8.1 and later
Informix IDS 9.40 and later

The following databases are supported in bi-directional snapshot replication:

SQL Server 2000 and later
Oracle 8i and later
IBM DB2 8.1 and later

DBMS-specific notes:

1. *SQL Server 2000 and later* Bi-directional snapshot triggers for SQL Server require "nested triggers" server option to be "On" (which is "On" by default).
2. *Oracle 8i*

   a. Oracle 8i does not have support for "localtimestamp" data type out of box. Required functionality can be enabled by editing $ORACLE_HOME/rdbms/admin/standard.sql script. The following statement

   ```
   pragma new_names('8.1.6',
                    dbtimezone, sessiontimezone, localtimestamp,
                    localtime, to_local_tz, to_db_tz,
                    cube, rollup, grouping, "TIMESTAMP WITH LOCAL TIME ZONE");
   ```

   should be changed to

   ```
   --pragma new_names('8.1.6',
   --                  dbtimezone, sessiontimezone, localtimestamp,
   --                  localtime, to_local_tz, to_db_tz,
   --                  cube, rollup, grouping, "TIMESTAMP WITH LOCAL TIME ZONE");
   ```

   After $ORACLE_HOME/rdbms/admin/standard.sql is edited it should be executed with SYS user privileges:

```
$sqlplus SYS/CHANGE_ON_INSTALL @$ORACLE_HOME/rdbms/admin/standard.sql
```

where "CHANGE_ON_INSTALL" is password for user SYS.Oracle 9i and later has this type in the default installation and this step is not necessary.

b. ODBC driver from Oracle 8.1.6 (and earlier versions) is known to be buggy and may cause Virtuoso server to crash when snapshot replication with Oracle database is set up. ODBC driver from Oracle 8.1.7 and later is recommended.

c. Oracle ODBC driver uses Oracle NLS settings by default for determining decimal separator. If decimal separator in the locale is not '.' (period) there will be interoperability errors with Virtuoso. Oracle ODBC driver can be forced to use US Settings for numerics: open Oracle ODBC driver configuration dialog, select "Application" tab and set "Numeric Settings" to "Use US Settings".

3. *DB2 8.1 ESE*

a. FixPak 3 is recommended because ODBC driver from earlier DB2 8 versions may cause Virtuoso server to crash when BLOB columns exist in replicated tables.

b. DB2 CLI/ODBC driver uses default locale's decimal separator. If decimal separator in the locale is not '.' (period) Virtuoso fails to parse numeric values. The default behavior of the DB2 CLI/ODBC driver can be modified by specifying PATCH2 CLI/ODBC configuration keyword in the db2cli.ini initialization file. Add the following line to your DSN config in db2cli.ini:

```
PATCH2=15
```

This will force DB2 CLI/ODBC driver to always use period ('.') as decimal separator.

4. *Informix IDS 9.40* Informix IDS can't report current time in UTC. This may cause snapshot replication to fail when timezone change occurs. In order to set up snapshot replication with Informix server properly any of the following steps must be taken:

Informix server must be run in UTC time zone.

"snp_repl_time_offset" registry variable should be set to value greater than 60.

The second method may cause additional system load on updates and will cause transactions to be replayed out of order when timezone change occurs.

13.2.7. Data type mappings

Heterogeneous replication requires data type mapping to be performed when Virtuoso table is created on replica.

Table 13.1. Data type mappings

Virtuoso	*SQL Server*	*Oracle*	*DB2*	*Informix*
varchar	varchar(8000)	VARCHAR2(4000)	VARCHAR(32000)	VARCHAR(254)
varchar(n)	varchar(n)	VARCHAR2(n)	VARCHAR(n)	VARCHAR(n)
integer	int	INTEGER	INTEGER	INTEGER
smallint	smallint	SMALLINT	SMALLINT	SMALLINT
real	real	FLOAT	REAL	SMALLFLOAT
double precision	float	DOUBLE PRECISION	DOUBLE	FLOAT
numeric	numeric(38, 15)	NUMERIC(38, 15)	NUMERIC(32, 15)	DECIMAL(31, 15)
numeric(p, s)	numeric(p, s)	NUMERIC(p, s)	NUMERIC(p, s)	DECIMAL(p, s)
date	datetime	DATE	DATE	DATE
time	datetime	DATE	TIME	DATETIME HOUR TO SECOND
datetime, timestamp	datetime	DATE	TIMESTAMP	DATETIME YEAR TO FRACTION(5)
varbinary	varbinary(8000)	RAW(2000)	VARCHAR(32000) FOR BIT DATA	BYTE
varbinary(n)	varbinary(n)	RAW(n)	VARCHAR(n) FOR BIT DATA	BYTE
long varbinary	image	BLOB	BLOB	BYTE

long varchar	text	CLOB	CLOB	TEXT
nvarchar	nvarchar(4000)	NVARCHAR2(4000)	VARCHAR(32000) FOR MIXED DATA	NVARCHAR(254)
nvarchar(n)	nvarchar(n)	NVARCHAR2(n)	VARCHAR(n) FOR MIXED DATA	NVARCHAR(n)
long nvarchar	ntext	NCLOB	DBCLOB	TEXT

13.2.8. Objects created by incremental snapshot replication

Table "DB.DBA.RPLOG_<name>" (replay log) is created in Virtuoso database for replayed snapshot log entries.

Table "RLOG_<name>" (snapshot log) is created in the source DSN. This table is attached as "<qual>"."<dsn>"."RLOG_<name>" if source table is an attached table. Other objects created by incremental snapshot replication in the source DSN are:

Virtuoso Triggers "<qual>_<owner>_<name>_I_log", "<qual>_<owner>_<name>_U_log" and "<qual>_<owner>_<name>_D_log" on replicated table.

SQL Server Triggers "<name>_I_log", "<name>_U_log" and "<name>_D_log" on replicated table.

Oracle Triggers "<name>_I_log", "<name>_U_log" and "<name>_D_log" on replicated table. Function OPL_GETUTCDATE().

DB2 Triggers "<name>_I", "<name>_U" and "<name>_D" on replicated table. Sequence opl_seq_rowguid.

Informix Triggers "<name>_I_log", "<name>_U_log" and "<name>_D_log" on replicated table. Sequence opl_seq_rowguid. Stored procedures "<name>_R_proc" and "<name>_U_proc".

13.2.9. Objects created by bi-directional snapshot replication

Table "DB"."DBA"."RPLOG_<name>" (replay log) is created in Virtuoso database for replayed snapshot log entries.

Table "RLOG_<name>" (snapshot log) is created on the publisher and on subscribers. "RLOG_<name>" table and replicated table itself are attached from subscribers as "<qual>"."<dsn>"."RLOG_<name>" and "<qual>"."<dsn>"."<name>" respectively. Other objects created by bi-directional snapshot replication on the publisher and on subscribers are:

Virtuoso Triggers "<qual>_<owner>_<name>_I_log", "<qual>_<owner>_<name>_U_log" and "<qual>_<owner>_<name>_D_log" on replicated table.

SQL Server Triggers "<name>_I_log", "<name>_U_log" and "<name>_D_log" on replicated table.

Oracle Triggers "<name>_I_log", "<name>_IR_log", "<name>_U_log", "<name>_UR_log", "<name>_UD_log", "<name>_UDR_log", and "<name>_D_log" on replicated table. Function OPL_GETUTCDATE(). Global temporary table "DLOG_<name>".

DB2 Triggers "<name>_I", "<name>_U", "<name>_UD" and "<name>_D" on replicated table. Sequence opl_seq_rowguid.

13.2.10. Replication system tables

SYS_SNAPSHOT

```
CREATE TABLE SYS_SNAPSHOT (
    SN_NAME     VARCHAR(255),
    SN_QUERY    VARCHAR(1024),
    SN_LAST_TS  VARBINARY(30),
    SN_IS_INCREMENTAL   INTEGER,
    SN_SOURCE_TABLE     VARCHAR(255),
    PRIMARY KEY (SN_NAME))
```

This table describes all defined snapshot replication relations. SN_NAME is the snapshot's name (destination table name). SN_QUERY is the query to get the data from. SN_LAST_TS is the time of the last update reflected for incremental snapshots (from the snapshot log's SNAPTIME). SN_IS_INCREMENTAL is null for nonincremental snapshots and non-null for the incremental ones. SN_SOURCE_TABLE is the source table for the incremental snapshots, NULL otherwise.

This implies that an incremental snapshot can be updated in two ways - incrementally and nonincrementally as the nonincremental definition is a subset of the incremental definition.

SYS_SNAPSHOT_LOG

```
CREATE TABLE SYS_SNAPSHOT_LOG (
    SNL_SOURCE  varchar (320) NOT NULL,
    SNL_RLOG    varchar (320) NOT NULL,
    SNL_RPLOG   varchar (320) NOT NULL,
    primary key (SNL_SOURCE)
)
```

This table describes all defined snapshot replication relation logs. SNL_SOURCE is the base table for which a snapshot log is defined. SNL_RLOG is the name of the RLOG snapshot log auxiliary table. SNL_RPLOG is the name of the RPLOG snapshot log auxiliary table.

13.2.11. Table snapshot logs

In order to be able to create incremental snapshots on a table there should be a snapshot log table defined in the following fashion:

```
create table RLOG_sourcetable (
RLOG_sourcetable_primarykey_parts,
...
SNAPTIME DATETIME,
DMLTYPE  CHAR(1),
RLOG_ROWGUID VARCHAR(255),
PRIMARY KEY (RLOG_*));
```

The name of the snapshot log table is constructed from the name of the source table by prefixing it with RLOG_ .

Snapshot log table contains all the primary key parts of the source table prefixed with RLOG_ .

Snapshot log table contains at most one row per updated source table row with the update time and update type in DMLTYPE (I - for insert, U - for update, D - for delete).

Snapshot log table contains RLOG_ROWGUID column which uniquely identifies this snapshow log row.

An updating procedure for incremental snapshot or bi-directional snapshot (table case) reads records from snapshot log table, ordered by SNAPTIME. Commits are performed each time an updating procedure notices that SNAPTIME has changed. In Virtuoso case (when native table is snapshot-replicated) all snapshot log records with equal SNAPTIME belong to the same transaction and all such records constitute almost a transaction (it is not exactly a transaction because only the last DML operation for each primary key in the source table is recorded in snapshot log table). So in Virtuoso case an updating procedure commits almost per transaction on source table. Snapshot log records are not transaction-bound in heterogeneous case however. Nevertheless, the technique used to determine when to commit described above prevents running out of transaction log or deadlocks even in heterogeneous case.

Replay log is created on the server which performs sync (server on which snapshot log was create in ordinary case, publisher in bi-directional snapshot case) to handle correct snapshot log replaying. Replay log is purged periodically using `REPL_PURGE_RPLOGS()` function in ordinary case and `REPL_PURGE_URPLOGS()` in bi-directional case. The calls to this functions are automatically scheduled when snapshot log or bi-directional snapshot publication is created and there is no need to call them manually.

There should be triggers on the source table to update the log like that:

```
create trigger xxx_I_log after insert on xxx
{
  insert replacing RLOG_xxx values (xxx_pk, now(), 'I', uuid());
};

create trigger xxx_D_log after delete on xxx
{
  insert replacing RLOG_xxx values (xxx_pk, now(), 'D', uuid());
};

create trigger xxx_U_log after update on xxx
{
  if (OLD.xxx_pk differs from NEW.xxx_pk)
    {
      insert replacing RLOG_xxx values (OLD.xxx_pk, now(), 'D', uuid());
```

```
      insert replacing RLOG_xxx values (NEW.xxx_pk, now(), 'I', uuid());
    }
  else
    insert replacing RLOG_xxx values (xxx_pk, now(), 'U', uuid());
};
```

where xxx is the source table name, RLOG_xxx is the snapshot log table name, xxx_pk is a comma separated list of the source table's primary key parts. The names of the triggers are constructed from the fully qualified name (DB.DBA.Orders makes DB_DBA_Orders_I_log).

Table snapshot logs and triggers are created automatically for Virtuoso and databases listed in Heterogeneous Snapshot Replication section.

13.3. Transactional Replication

The unit of replication is a publication. A publication is an ordered sequence of transaction entries. One database transaction can add data to zero or more publications. The data contributed to a publication by a transaction is appended to the publication at the time of commit. Because commits are serialized database wide, items in a publication have a well defined order.

Each transaction entry in a publication has a unique sequence number within the publication. Each subscriber of a publication has a level of synchronization, which is the serial number of the last transaction from the publication which this subscriber has processed.

Each publication has exactly one publisher and zero or more subscribers. Any multi-master merge replication schemes will be based on this notion, with data to be merged back into the original source regarded as a separate publication and the merge regarded as a process between publications.

In order to publish data for replication by others a server must have a unique name within the group of servers participating in the replication. This server name is assigned to the server in its virtuoso.ini file in the DBName setting.

To publish data the publishing server initializes a publication with the repl_publish function, where it names the publication and assigns a log file name for it. The server can then start adding transactions to the publication, which can happen either under application control or implicitly.

Tip

See the repl_text function.

To subscribe to publications a server must also have a distinct DBName. It identifies the publishing server by associating a host name and port number to its logical name with the repl_server function. It can then call `repl_subscribe()` . Replication feeds from publisher are replayed by 'dba' user by default. The default can be changed (see repl_subscribe() function). for each of the publications it subscribes to. A publication is uniquely identified on the subscriber with the publishing server name and the publication name. Note that several servers in a network may publish like named publications and these will be logically distinct, having each their own distinct publisher.

A subscriber may or may not be connected to the publisher at any point in time. If a subscriber is connected to the publisher it may either be 'in sync' or syncing'. In the syncing state it is receiving transaction entries with numbers consecutive from its sync level up until the last committed serial number committed on the server.

At the start of the sync communication the subscriber indicates the level of the last successfully processed transaction in the publication. The sync exchange terminates when the subscriber reaches the last committed item on the publication. At this point the subscriber is said to be 'in sync'. The connection to the publisher is then maintained by default and is used to send sync information as it becomes available. This means that once an entry is appended to the publication by a committing a transaction it is sent to the 'in sync' subscribers without separate request.

The publisher can terminate the replication feed by unilateral decision. It will do it if the sending of the message times out for too long or if the queue of 'to be sent' replication records exceeds a settable threshold. This essentially happens with communication failures or if the subscriber continuously processes the feed at a speed lower than the feed production speed of the publisher. A disconnected subscriber can reconnect at will, in which case it enters the 'syncing' state and will receive transactions from the point where the feed was cut.

A subscriber can disconnect from the publisher at any time without ill effect.

A table

```
SYS_REPL_ACCOUNTS (
    SERVER varchar,
    ACCOUNT varchar,

    NTH integer,
    LEVEL integer,
    IS_MANDATORY integer,
    IS_UPDATEABLE integer,
    SYNC_USER varchar,

    P_MONTH integer,
    P_DAY integer,
    P_WDAY integer,
    P_TIME time,

    primary key (SERVER, ACCOUNT))
```

is used to store information about published accounts and accounts this server is subscribed to.

A table

```
SYS_REPL_SUBSCRIBERS (
    RS_SERVER varchar,
    RS_ACCOUNT varchar,
    RS_SUBSCRIBER varchar not null,

    RS_LEVEL integer NOT NULL,
    RS_VALID integer NOT NULL,

    primary key (RS_SERVER, RS_ACCOUNT, RS_SUBSCRIBER))
```

is used to store subscribers' status (pushback accounts for updateable subscriptions are there too). Subscribers for an account are added to this table automatically on each request to sync an account from subscriber or manually from Admin UI.

SYS_REPL_SUBSCRIBERS.RS_VALID column is be used to designate subscribers whose replication account level is valid (lags not more than REPL_MAX_DELTA behind the publisher's level).

RS_VALID state of subscriber is checked and updated on every sync request from subscriber. If subscriber is found to be invalid all further sync requests from it are ignored. Such subscriber need to be reinitialized manually and marked as valid using Admin UI.

13.3.1. Publishable Items

Tables, stored procedures and DAV collections may be added to a transactional publication. When a table is added, triggers are created for capturing changes to the table. When a procedure is added, all calls to this procedure will be recorded in the publication's log and the same procedure will be called on the subscriber. When a procedure is published in this manner, actions performed inside the procedure are not themselves recorded even if they touch on items that are part of a publication. It is assumed that the procedure on the subscriber will produce the equivalent effect. When a DAV collection is published, operations on direct and indirect members of the collection are logged into the publication's log. When this is replayed on the subscriber, the operations are repeated on like-named DAV resources, creating collections and resources as needed.

When a table or procedure is added to a publication, the creating statement is added also, so that the subscribers come to create the table or procedure before receiving any replication operations on said table or procedure. Also when the table or procedure is altered, the altering statements are added to the publication so s to be reflected on all subscribers. This can be overridden for procedures, since in some cases it is desirable to have a different definition on the subscriber. Table constraints are also replicated, except for foreign key constraints with tables outside the publication, since these would not be meaningful on the subscriber, as there is no knowledge on what tables may exist there outside of the ones in the publication. Changes to schema on subscribers are never replicated to the publisher, even if we had bidirectional replication. Identity and timestamp columns are replicated so that the values on the subscriber are assigned by the publisher.

When a procedure is published, it is possible to specify whether the definitions, calls or both are replicated. Usually specifying both calls and definition is reasonable, sometimes only calls are to be replicated if the procedure intentionally has a different definition in the subscriber. This is useful for example when the subscriber gathers statistics or maintains a data warehouse where

the storage schema is not identical with that of the publisher. Only procedures with input parameters can be replicated. The rationale is that replication is a one way stream and no return values, result sets or output parameters can be captured by either publisher or subscriber. Procedure calls cannot be replicated bidirectionally, these go from publisher to subscriber exclusively.

Even though replication can carry schema changes, it is in no way a means of keeping software installations in sync. Many schema elements such as triggers are not covered and a software upgrade is more complex than can be represented by replication alone.

13.3.2. Errors in Replication

A statement received for replication from a publisher may encounter an error. All Such errors are logged into the subscriber's error log file. If the error is retryable, like a deadlock, retries are made until the operation succeeds. If Other errors are simply skipped and replication proceeds. A replication subscription can be permanently broken and out of sync if for example columns are dropped from the subscriber copy of the tables or if the subscriber runs out of disk and can replay some transactions but not all. Note that in such situations gaps may be formed into the received transaction sequence. In such cases, it is best to drop the subscription, drop the tables and remake the subscription.

13.3.3. Publisher Transactional Replication Functions

The most generic form of the replication element is a stored procedure call. This associates a procedure name and set of parameters to a publication inside a transaction. When the transaction commits, all the publication entries are appended to the publication, forming a replication entry with its unique number.

These functions are available to the publishing Virtuoso server:

- `repl_publish()`
- `repl_unpublish()`
- `repl_pub_add()`
- `repl_pub_remove()`
- `repl_pub_init_image()`
- `repl_new_log()`
- `repl_text()`
- `repl_grant()`
- `repl_revoke()`

13.3.4. Subscriber Functions

These are the functions that are available to the subscribing Virtuoso server:

- `repl_server()`
- `repl_subscribe()`
- `repl_unsubscribe()`
- `repl_init_copy()`
- `repl_sync()`
- `repl_sync_all()`
- `repl_sched_init()`
- `sub_schedule()`
- `repl_disconnect()`
- `repl_this_server()`
- `repl_purge()`

13.3.5. Common Status Functions

- `repl_stat()`
- `repl_status()`

The status () function shows a replication status summary. The same data can be obtained with the repl_stat and repl_status procedures.

13.3.6. Bi-Directional Transactional Replication

Virtuoso supports bi-directional transactional replication via a mechanism of updateable subscriptions. The following rules and conditions must be observed:

Every table has only one publisher.

Only direct subscribers are considered.

Only replication of tables is allowed.

It is assumed that all the tables within a publication have primary keys and that the primary key columns are never modified.

Every transaction has an origin, i.e. the originating server on which the transaction was performed.

Modifications to a subscriber come from publisher only using the ordinary transactional replication technique: the subscriber initiates an update and pulls (requests) replication logs from publisher. The publisher sends the replication log from the replication log files and then places the subscriber into "synced" (or "online") mode. In this mode the replication logs are sent to subscriber immediately after each COMMIT.

Data flow from a subscriber to the publisher is very similar: the subscriber initiates the update and pushes replication logs to the publisher. After all replication log data has been sent to the publisher it is put into "synced" mode and will receive modifications immediately after each COMMIT on subscriber.

Creating Publications for Updateable Subscriptions

In order to create a publication that allows transaction-based replication and updateable subscriptions use the `repl_publish()` with a non-zero third argument. Replication feeds from subscribers can be replayed by user different from 'dba' user.

```
repl_publish('foo', 'foo.log', 1, 'demo');
```

This will create updateable publication 'foo'. Replication feeds from subscribers will be replayed as user 'demo'.

Adding Tables to a Publication

When a table is added to an updateable publication a new 'ROWGUID varchar' column is automatically added to the table. This column will be used for conflict resolution (described later). If the table already has column with such a name, an existing column will be used (with checking for appropriate data type and width). ROWGUID columns hold globally unique identifiers of a row and are modified after each UPDATE of a row. ROWGUID column values are OSF DCE 1.1 compliant Universally Unique Identifiers (UUID).

ROWGUID columns are used for conflict resolution for INSERT/UPDATE/DELETE DML operations. Basically, if a ROWGUID column that came from a subscriber does not differ from the ROWGUID column of the publisher's table then it is assumed that there is no conflict, otherwise conflict resolution must take place.

Conflict Resolution

Since every table may have only one publisher, conflicts resolution will always take place on the publisher.

Assume some DML operation that occurred on a subscriber is being replayed on publisher. There may be three types of conflicts:

1. **uniqueness conflict (insert conflict) .** occurs when the row with some primary key <PK> already exists in publisher's table.
2. **update conflict .** occurs when an UPDATE modifies a row which has already been modified on publisher (by the publisher or another subscriber).
3. **delete conflict .** occurs when an UPDATE modifies a row or a DELETE removes a row that does not exist on publisher anymore.

Every table has a number of conflict resolvers that are used for conflict resolution. These are stored in DB.DBA.SYS_REPL_CR system table. Each conflict resolver has a type ('I', 'U', or 'D') and an order. Conflict resolvers are applied in ascending order.

The conflict resolver is a Virtuoso/PL procedure that receives a conflicting row from a subscriber and some other arguments. The conflict resolver can modify the row, which is passed as an 'inout' argument. The conflict resolver should return an integer value,

which will be used for conflict resolution.

Conflict resolvers of different types have different signatures:

'I' - Insert conflict resolvers (<ALLCOLS>, inout _origin varchar)
'U' - Update conflict resolvers (<ALLCOLS>, , <ALLOLDCOLS>, inout _origin varchar)
'D' - Deletion conflict resolvers (<ALLOLDCOLS>, inout _origin varchar)
where

<ALLCOLS> are new values of all columns including the ROWGUID column, <ALLOLDCOLS> are old values of all columns, and _origin is transaction originator.

Conflict resolvers can return the following integer values; The conflict resolver types concerned for each are listed in parentheses:

- **0 - can't decide (I, U, D) .** next conflict resolver will be fired.
- **1 - subscriber wins (I, U, D) .** DML operation will be applied with <ALLCOLS> All the subscribers except originator will receive modifications (originator already has them).
- **2 - subscriber wins, change origin (I, U) .** DML operation will be applied with <ALLCOLS> and origin of transaction will be changed to publisher's server name. All the subscribers (including originator) will receive modifications. This return value is useful when conflict resolver changed some of the columns of the row that were passed in. Although all parameters of conflict resolver are inout only changing of <ALLCOLS> (non-PK columns) parameters makes sense.
- **3 - publisher wins (U) .** DML operation will be applied with <ALLCOLS> taken from publisher's table. All the subscribers will receive modifications.
- **4 - reserved .**
- **5 - ignore (D) .** DML operation is ignored.

Conflict resolution stops when conflict resolvers return a non-zero value meaning that it has made a decision.

Example 13.5. Conflict Resolution

Suppose we have the following table:

```
create table items(
  item_id integer primary key,

  name varchar,
  price decimal
);
```

"Publisher wins" 'I' conflict resolver will look like:

```
create procedure items_cr(
    inout _item_id integer,
    inout _name varchar,
    inout _price decimal,
    inout _origin varchar)
  returns integer
{
  return 3;
}
```

The conflict resolver that will make a decision based on the minimal price column will look like:

```
create procedure items_cr(
    inout _item_id integer,
    inout _name varchar,
    inout _price decimal,
    inout _rowguid varchar,
    inout _old_item_id integer,
    inout _old_name varchar,
    inout _old_price decimal,
    inout _old_rowguid varchar,
    inout _origin varchar)
  returns integer
{
```

```
  declare p decimal;
  -- get current price value
  select price into p from items where item_id = _item_id;
  if (p < _price)
    return 3;                   -- publisher wins
  else if (p > _price)
    return 1;                   -- subscriber wins
  return 0;                     -- can't decide
}
```

Conflict resolver that will change the price to the minimal value will look like:

```
create procedure items_cr(
    inout _item_id integer,
    inout _name varchar,
    inout _price decimal,
    inout _rowguid varchar,
    inout _old_item_id integer,
    inout _old_name varchar,
    inout _old_price decimal,
    inout _old_rowguid varchar,
    inout _origin varchar)
  returns integer
{
  declare p decimal;
  -- get current price value
  select price into p from items where item_id = _item_id;
  if (p < _price)
    {
      _price := p;
      return 2;                 -- publisher wins, change origin
    }
  return 1;                     -- subscriber wins
}
```

Conflict resolution occurs differently for each kind of DML operation:

- **INSERT .** When INSERT of some row with primary key <PK> is replayed, the row in the publisher's table with such <PK> is looked-up. If the row does not exist then there is no conflict, conflict resolution stops and the INSERT is replayed. If the row exists then we have a "uniqueness conflict". In this case 'I' conflict resolvers are fired-up. If none of the 'I' conflict resolvers were able to make a decision (return non-zero value) the default action is 'publisher wins'.
- **UPDATE .** When there is an UPDATE of some row with primary key <PK> is replayed, the row (and its ROWGUID) in publisher's table with such <PK> is looked-up. If the row does not exist then we have a "delete conflict", 'D' conflict resolvers are fired up. If none of the 'D' conflict resolvers were able to make a decision the default action will be to 'ignore'. If the row exists in the publisher's table and its ROWGUID is the same as that from the subscriber then there is no conflict. Conflict resolution stops and the UPDATE is replayed. If the row exists and its ROWGUID differs from the one that came from subscriber then we have an "update conflict". In this case the 'U' conflict resolvers are fired-up. If none of the 'U' conflict resolvers were able to make a decision (return non-zero value) the default action will be 'publisher wins'.
- **DELETE .** When DELETE of some row with primary key <PK> is replayed, the row in the publisher's table with such <PK> is looked-up. If the row does not exist or if the row exists but its ROWGUID differs from the one that came from subscriber then we have "delete conflict". The 'D' conflict resolvers are fired-up. If none of the 'D' conflict resolvers were able to make a decision then the default action will be taken to 'ignore'. Otherwise it is assumed that there is no conflict and DELETE statement is replayed.

Automatically Generated Conflict Resolvers

Simple conflict resolvers can be generated automatically. This can be done by calling REPL_ADD_CR function.

See Also:

`REPL_ADD_CR()`

Replication Log Data

Replication log data is different for each kind of DML operation:

- **INSERT.** (stmt, <ALLCOLS>)
- **UPDATE.** (stmt, <ALLCOLS>, <OLDPK>, <ALLOLDCOLS>, ncols)
- **DELETE.** (stmt, <OLDPK>, <ALLOLDCOLS>, ncols)

where

stmt is DML statement (varchar), <ALLCOLS> is new values of all columns, <OLDPK> is primary key, specifying a row for which (UPDATE or DELETE) DML statement is executed, <ALLOLDCOLS> is old values of all columns, ncols is number of columns in table (integer).

The format of the log replication data is the same as in simple transactional replication with addition of <ALLOLDCOLS> and ncols for logging UPDATE and DELETE statements.

13.3.7. Purging replication logs

Every replication account has an associated sequence which holds replication account level (basically, transaction number). Each subscriber also maintains a sequence where it stores its replication account level.

When subscriber issues a sync request for an account it submits its replication account level so publisher can find a point in time from where it should start to submit replication logs to publisher.

Replication account level can roll over REPL_WRAPAROUND (0x7fffffff) to 1. Old replication logs need to be purged to allow this to work correctly. Procedure repl_purge() purges replication logs for a specified account.

Columns needed to store purger configuration in SYS_REPL_ACCOUNTS table are:

P_MONTH integer (month, nullable)

P_DAY integer (day of month, nullable)

P_TIME time (time, nullable)

If P_TIME is NULL log purger will not be scheduled to run at all. If P_TIME is not NULL there can be the following combinations of P_MONTH, P_DAY and P_WDAY ('*' means NULL value, 'x' means any value):

Table 13.2. Purger config settings

P_MONTH	*P_DAY*	*P_WDAY*	*meaning*
month	day	x	purger is run yearly on specified month and day
month	*	x	purger is run yearly on 1st of month
*	day	x	purger is run monthly on specified day of month
*	*	wday	purger is run weekly on specified day of week
*	*	*	purger is run daily

An entry to call purger is inserted (or updated) into SYS_SCHEDULED_EVENT after each modification of purger settings for an account (from Admin UI) or after each successful run of repl_purge() for this account.

13.3.8. Objects created by transactional replication

Virtuoso creates triggers "<name>_I", "<name>_U" and "<name>_D" for every published table. On subscriber "DB"."DBA"."SYS_REPL_ACCOUNTS" table and "DB"."DBA"."TP_ITEM" view are attached from publisher as "DB"."<dsn>"."SYS_REPL_ACCCOUNTS" and "DB"."<dsn>"."TP_ITEM" respectively.

If publication is updateable Virtuoso additionally creates the following objects:

"<qual>"."<owner>"."replcr_<name>_I", "<qual>"."<owner>"."replcr_<name>_U" and "<qual>"."<owner>"."replcr_<name>_D" procedures for every published table. These procedures are used for conflict resolution.

Triggers "<name>_I", "<name>_U" and "<name>_D" for every subscribed table.

13.4. Virtuoso scheduler

Virtuoso scheduler allows an arbitrary SQL command to be run at certain intervals.

The scheduler process wakes up every n minutes, scans the SYS_SCHEDULED_EVENT table and executes each command which applies to the current time. Note that overdue commands are executed only once.

There is a virtuoso.ini parameter "SchedulerInterval" under Parameters section which defines the scheduler wake-up interval. Set this to 0 (the default) to disable the scheduler.

13.4.1. SYS_SCHEDULED_EVENT

```
CREATE TABLE SYS_SCHEDULED_EVENT(
    SE_NAME             varchar,
    SE_START            datetime,
    SE_SQL              varchar,
    SE_LAST_COMPLETED   datetime,
    SE_INTERVAL         integer,
    PRIMARY KEY(SE_NAME));
```

This table describes each scheduled SQL command. SE_NAME is the name of the scheduled event. SE_START is the first schedule execution time. SE_SQL is the text of the SQL command to be executed. SE_LAST_COMPLETED is the last time when the SQL command was executed successfully. SE_INTERVAL is the interval between the runs of the SQL command in minutes.

Defining a new scheduled event means adding a row to the SYS_SCHEDULED_EVENT with an insert statement like this:

```
INSERT INTO SYS_SCHEDULED_EVENT (SE_NAME, SE_SQL, SE_START, SE_INTERVAL)
                VALUES (.....)
```

13.5. Transactional Replication Example

```
-- ================================
-- ON PUBLISHER SIDE (named 'rep1')
-- ================================
set DSN=1111;
reconnect;
-- Create test tables & fill with data
create table DB.DBA.TEST (id integer, name varchar, tm datetime,
        content long varchar, primary key (id, name));
create table "ab ""cd" ("id key" integer, "ef ""gh" varchar, primary key ("id key"));
insert into DB.DBA.TEST values (1, 'a', now(), 'xxx');
insert into DB.DBA.TEST values (1, 'b', now(), 'xxx');
insert into DB.DBA.TEST values (1, 'c', now(), 'xxx');
insert into DB.DBA.TEST values (1, 'd', now(), 'xxx');
insert into "ab ""cd" values (1,'1');
-- Public one account named 'dav'
REPL_PUBLISH ('dav', 'dav.log');
-- Add an existing collection '/DAV/repl' into the 'dav' publication
REPL_PUB_ADD ('dav', '/DAV/repl/', 1, 0, null);
-- Public second account named 'tbl' for tables'
REPL_PUBLISH ('tbl', 'tbl.log');
-- Add 'TEST' table into the 'tbl' publication account
REPL_PUB_ADD ('tbl', 'DB.DBA.TEST', 2, 0, null);
-- Add 'ab "cd' table into the 'tbl' publication account
REPL_PUB_ADD ('tbl', 'DB.DBA.ab "cd', 2, 0, null);

-- ================================
-- ON SUBSCRIBER SIDE (named 'rep2')
-- ================================
set DSN=1112;
reconnect;
```

```
-- Add publication server named 'rep1' with DSN '1111' placed
-- on 'localhost' machine and using port '1111'
REPL_SERVER ('rep1', '1111', 'localhost:1111');
-- Add subscription for 'dav' publication account
REPL_SUBSCRIBE ('rep1', 'dav', null, null, 'dba', 'dba');
-- Perform initial copy of publication 'dav' data
DB..REPL_INIT_COPY ('rep1', 'dav');
-- Add subscription for 'tbl' publication
REPL_SUBSCRIBE ('rep1', 'tbl', null, null, 'dba', 'dba');
-- Perform initial copy of publication 'tbl' data
DB..REPL_INIT_COPY ('rep1', 'tbl');

-- Now we look at copied data (should return 4)
select count(*) from TEST;
-- And second table (should return 1)
select count(*) from "ab ""cd";

-- Turn subscription in 'SYNC'
SYNC_REPL();

-- ================================
-- ON PUBLISHER SIDE (named 'rep1')
-- ================================
set DSN=1111;
reconnect;
-- Insert an additional data
insert into DB.DBA.TEST values (7,'a',now(), repeat('x',1000000));
insert into "ab ""cd" values (2,'2');
insert into "ab ""cd" values (3,'3');
insert into "ab ""cd" values (4,'4');
delete from "ab ""cd" where "id key" = 4;
update "ab ""cd" set "ef ""gh" = '4' where "id key" = 3;

-- ================================
-- ON SUBSCRIBER SIDE (named 'rep2')
-- ================================
set DSN=1112;
reconnect;
-- make a procedure to check status of subscription
create procedure WAIT_FOR_SYNC (in srv varchar, in acct varchar)
{
  declare level, stat integer;
  stat := 0;
  while (level < 6)
    {
      repl_status (srv, acct, level, stat);
      if (stat = 3)
        SYNC_REPL ();
    }
};
-- run it till subscription got the right level of synchronization
WAIT_FOR_SYNC ('rep1', 'tbl');

-- Check the data (should return 5)
select count (*) from DB.DBA.TEST;
-- Check the data (should return 3)
select count(*) from "ab ""cd";

-- Check the new data entered on publisher (will return 4)
select "ef ""gh" from "ab ""cd" where "id key" = 3;

-- Check the old data deleted from publisher (will return 0)
select count(*) from "ab ""cd" where "id key" = 4;

-- ================================
-- ON PUBLISHER SIDE (named 'rep1')
-- ================================
set DSN=1111;
reconnect;
-- Create an table to use for procedure calls
create table p_test (id integer, dt varchar, primary key (id));
insert into  p_test values (1, '1');
insert into  p_test values (2, '2');
```

```
insert into  p_test values (3, '3');
insert into  p_test values (4, '4');
insert into  p_test values (5, '5');
-- And an procedure which inserts records in p_test table
create procedure t_proc (in i integer)
{
  declare d varchar;
  select dt into d from p_test where id = i;
  d := concat (d, d);
  update p_test set dt = d where id = i;
};

-- Make an account named 'proc' for procedure replication
REPL_PUBLISH ('proc', 'proc.log');
-- Add 't_proc' procedure into 'proc' publication
REPL_PUB_ADD ('proc', 'DB.DBA.t_proc', 3, 0, 3);

-- ================================
-- ON SUBSCRIBER SIDE (named 'rep2')
-- ================================
set DSN=1112;
reconnect;
-- crate the same table on subscriber
create table p_test (id integer, dt varchar, primary key (id));
-- insert an data into it
insert into  p_test values (1, '1');
insert into  p_test values (2, '2');
insert into  p_test values (3, '3');
insert into  p_test values (4, '4');
insert into  p_test values (5, '5');
-- Add subscription for 't_proc' publication
REPL_SUBSCRIBE ('rep1', 'proc', null, null, 'dba', 'dba');
-- Perform initial copy of procedure definition
DB..REPL_INIT_COPY ('rep1', 'proc');
-- Turn all subscriptions in 'SYNC' state
SYNC_REPL();

-- ================================
-- ON PUBLISHER SIDE (named 'rep1')

reconnect;
-- call 5 times 't_proc'
t_proc(1);
t_proc(2);
t_proc(3);
t_proc(4);
t_proc(5);

-- ================================
-- ON SUBSCRIBER SIDE (named 'rep2')
-- ================================
set DSN=1112;
reconnect;
-- create an procedure to check synchronization level
create procedure WAIT_FOR_SYNC (in srv varchar, in acct varchar, in n integer)
{
  declare level, stat integer;
  stat := 0;
  while (level < n)
    {
      repl_status (srv, acct, level, stat);
    }
};
-- and run it till level set to 5
WAIT_FOR_SYNC ('rep1', 'proc', 5);

-- check local data (should return 5)
select count(*) from p_test where length (dt) = 2;

-- ================================
-- ON PUBLISHER SIDE (named 'rep1')
-- ================================
```

```
set DSN=1111;
reconnect;
-- modify procedure to insert 123 new records
create procedure t_proc (in i integer)
{
  declare d varchar;
  declare n integer;
  n := 128;
  while (n > 5)
    {
      insert into p_test (id, dt) values (n, cast (n as varchar));
      n := n - 1;
    }
};
-- and call it once
t_proc (1);

-- ================================
-- ON SUBSCRIBER SIDE (named 'rep2')
-- ================================
set DSN=1112;
reconnect;
-- and run check routine till level set to 7
WAIT_FOR_SYNC ('rep1', 'proc', 7);
-- check  local data (should return 128, old 5 + 123 new records)
select count(*) from p_test;
```

13.5.1. Transactional Replication Objects Example

Preconditions

publisher named 'rep' with replication address 'localhost:1111'

subscriber named 'sub'

on subscriber should be defined DSN for rep named '1111'

On publisher side. Creating publication

```
SQL> REPL_PUBLISH ('pub', 'pub.log');

-- Add row in SYS_REPL_ACCOUNTS table
SQL> select SERVER, ACCOUNT from SYS_REPL_ACCOUNTS
        where ACCOUNT = 'pub';

SERVER ACCOUNT
--------------
rep    pub
```

started new replication log file in server working directory named 'pub.log'

add entry in repl.cfg in server working directory

```
SQL> REPL_PUB_ADD ('pub', 'DB.DBA.TEST', 2, 0, null);

SQL> select * from SYS_TP_ITEM;

TI_SERVER TI_ACCT TI_TYPE TI_ITEM     TI_OPTIONS TI_IS_COPY
_____________________________________________________________
rep       pub     2       DB.DBA.TEST NULL       0
```

Adding items to the publication

Add row in SYS_TP_ITEM

On Subscriber Side. Adding a new publisher

```
SQL> REPL_SERVER ('rep', '1111', 'localhost:1111');

-- Add row in SYS_SERVERS
```

```
SQL> select * from SYS_SERVERS;

SERVER                    DB_ADDRESS                REPL_ADDRESS
------------------------------------------------------------------
rep                       1111                      localhost:1111

   SQL> REPL_SUBSCRIBE ('rep', 'pub', 'dav', 'dav_group', 'uid_for_rep', 'uid_pwd_for_rep');
```

'publication and subscription servers have identical names.' if subscriber and publisher have the same names.
'Publishing server must be declared with REPL_SERVER before subscribing' if publisher 'rep' is not defined from previous step.
'The subscription 'pub' already exist' if on subscriber 'sub' already exists subscription 'pub'
'User name and password should be supplied when subscribe to new publisher' if 'uid_for_rep' or 'uid_pwd_for_rep' not supplied
'The table 'DB.DBA.TEST' already exists' if on subscriber 'sub' already exist table in subscription.
'The WebDAV collection '/DAV/rep/' already exists' if on 'sub' already exist WebDAV collection in subscription.
a VDB error message if subscriber 'sub' cannot perform attaching TI_ITEM view from publisher 'pub'

```
SQL> select * from SYS_TP_ITEM where TI_ACCT = 'pub'

TI_SERVER TI_ACCT TI_TYPE TI_ITEM    TI_OPTIONS TI_IS_COPY TI_DAV_USER TI_DAV_GROUP
_____________________________________________________________________________
rep       pub     2       DB.DBA.TEST NULL       0           dav       dav_group

SQL> select SERVER, ACCOUNT from SYS_REPL_ACCOUNTS where ACCOUNT = 'pub';

SERVER ACCOUNT
--------------
rep    pub
```

Making a subscription

This may signal an SQL error if a precondition is not met.

Add row in SYS_TP_ITEM and row in SYS_REPL_ACCOUNTS

13.6. Replication Logger Sample

The logger directory in the samples in the distribution contains a simple load balancing sample. It implements a simplified web site hit log where there is a count of hits maintained per user name and origin IP of each hit.

Thus the transaction being replicated between the servers consists of incrementing an IP's hit count and then incrementing a user's hit count. If either IP or user do not have a count, a row is added with a count of 1. The transaction is then logged for replication, so that all servers get all hits, no matter which of the replicating servers processes the hit.

```
create table wl_ip_cnt (ic_ip varchar, ic_cnt integer,
       primary key (ic_ip));

create table wl_user (wu_user varchar, wu_cnt integer,
       primary key (wu_user));

create procedure wl_hit_repl (in ip varchar, in usr varchar)
{
  set isolation = 'serializable';
  update wl_ip_cnt set ic_cnt = ic_cnt + 1 where ic_ip = ip;
  if (0 = row_count ())
    insert into wl_ip_cnt (ic_ip, ic_cnt) values (ip, 1);
  update wl_user set wu_cnt = wu_cnt + 1 where wu_user = usr;
  if (0 = row_count ())
    insert into wl_user (wu_user, wu_cnt) values (usr, 1);
}

create procedure wl_hit (in ip varchar, in usr varchar)
{
  wl_hit_repl (ip, usr);
  repl_text ('hits', 'wl_hit_repl (?, ?)', ip, usr);
}
```

The application client calls wl_hit on one of the mutually replicating servers to log an event. The event's trace will then be propagated to all other servers. The wl_hit_repl function does the actual work. The top level function calls this plus logs the call with its arguments on the local server's hits publication for distribution to other servers.

13.6.1. Configuration of the Sample

The following sequence of calls can be used to define a network of four servers, each replicating every other server. For the sake of example, they are all on localhost and listen at ports 2001 through 2004.

```
repl_server ('log1', 'localhost:2001');
repl_server ('log2', 'localhost:2002');
repl_server ('log3', 'localhost:2003');
repl_server ('log4', 'localhost:2004');

repl_publish ('hits', 'hits.log');

repl_subscribe ('log1', 'hits');
repl_subscribe ('log2', 'hits');
repl_subscribe ('log3', 'hits');
repl_subscribe ('log4', 'hits');
```

First all the servers are identified. Next the local server declares that it has a publication 'hits'. Next it subscribes to the hits publications of all other servers. In the process it also subscribes to itself, which signals an error and has no other effect.

In this way all servers share one configuration. Each server knows which of the servers it is based on the DBName setting in its virtuoso.ini file.

13.6.2. Synchronization

```
create procedure log_sync ()
{
  for select SERVER, ACCOUNT from SYS_REPL_ACCOUNTS do
    {
      if (SERVER <> repl_this_server ())
        {
          declare err, msg varchar;
          err := '00000';
          exec ('repl_sync (?, ?, ?, ?)', err, msg, vector (SERVER, ACCOUNT, 'dba', 'dba'), 0);
        }
    }
}
```

This procedure will go through all subscriptions and request sync for each. Note that the repl_sync function is called inside exec to catch any possible exceptions, as servers may not be available etc. For the sake of simplicity this supplies the literal default dba login 'dba', 'dba' as authentication.

The replication sample schedules a call to this function to be made every minute as a background job. if all replication servers are on line and in sync or syncing the function will return without delay or effect. Otherwise it will keep trying until it gets a connection.

13.6.3. Running the Sample

The logger directory contains various scripts for starting and stopping servers etc.

log_init.sh - Creates the databases with tables and procedures loaded in the l1, l2, l3 and l4 subdirectories.

log_start.sh - starts the 4 servers and leaves them running in the background.

log_shut.sh - Shuts down the 4 test servers.

hits.sh <hist-per-hour> <no-of-hits>

Starts the hits program on each of the 4 servers. The first command line argument gives the test transaction rate for each client and the next gives the duration as a transaction count.

```
hits <dsn> <uid> <pwd> <hits-per-hour> <no-of-hits>
```

The hits executable repeatedly calls wl_hit with random arguments and collects statistics on call times. If calls complete at a rate faster than the requested rate this periodically sleeps to keep the rate close to the requested rate. It prints statistics every 1000 hits.

13.6.4. Notes on the Sample's Dynamics

When the network initially starts all the publications are at level 0 and in sync. When transactions are fed into the network at a sufficiently slow rate all the servers get to process all transactions in real time. Note that the structure is such that every server does everybody else's work in addition to its own. Thus the insertion rate of the network can't be expected to be higher than that of an individual server. However read load can be spread across servers, so that this type of configuration is effective for balancing query load but not for balancing update load.

As we increase the transaction rate at each server we reach a point at which the queue of locally committed but un-replicated transactions grows faster than the other servers will absorb the feed. The servers will each eventually disconnect all synced replication to stop the queue from growing. Once the queue that no longer grows goes empty the subscribers get disconnected. At this point all servers only process their own load without any other distraction.

Next each server will notice that it is disconnected from the network and will attempt a resync as a result of the periodic scheduled call to log_sync. Each server will then re-establish a connection to every other server and start resyncing. This will lead to the network being again in sync if the per server transaction rate slows down sufficiently to allow replicators to catch up. If this does not happen the syncing can stay in progress indefinitely, until it either reaches sync or is terminated.

Typically a server's capacity for processing local transactions is greater than its capacity for replaying replication feed. This is because one thread is responsible for all replay activity while many threads can process local transactions.

The net result of this scheduling policy is that even a heavily replicated network will scale to high peak loads and will automatically return to sync state as soon as the peak is over. If guaranteed transaction level synchronicity must be maintained between servers then the application should not be written using transactional replication but rather with distributed transactions, where each commit makes sure the transaction is fully processed on each participant before returning to the client. This is however up to several times slower and will stop the entire network if a single node fails.

Chapter 14. Web Application Development

Abstract

This chapter deals with the Virtuoso HTTP Server, its Dynamic Page generation and components used to configure it. The HTTP Servers features include:

Web server configuration and access control.

Multihosting, Virtual Hosting and Virtual Directories - A single Virtuoso server can map requests into multiple spaces of web pages based on the interface to which the requests come (multihosting) or on the Host HTTP/1.1 header (virtual hosting).

HTTP/1.0 and HTTP/1.1 support, keep alive connections and pipelining.

Proxying - Virtuoso can automatically redirect requests to certain resources or directories to another web server.

Authentication and security - Specific directories can be made to require authentication (basic or digest) or may be restricted to SSL only. Authentication can also be totally user defined.

SOAP - given directories can be defined as containing SOAP services, which can be accessed by SOAP clients, invoking Virtuoso stored procedures.

Dynamic content - Given paths can be executable, allowing defining VSP, and VSPX pages that generate HTML or XML using embedded Virtuoso/PL.

WebDAV - Paths can be mapped into DAV collections maintained inside the database. Virtuoso WebDav is a Unix file system-like mechanism allows specifying access rights and ownership of DAV resources.

WebDAV resources may optionally be indexed in a free text index.

A web robot allows copying external web resources into Virtuoso WebDAV.

Virtuoso provides a full function web server with dynamic web page generation capability using SQL procedures embedded in HTML or XML via VSP or VSPX. Runtime hosting allows Virtuoso to generate dynamic web pages from other sources also, such as ASP.Net, PHP or JSP.

Out-of-the-box Virtuoso listens for HTTP requests on the port defined in the HTTP Server section of the Virtuoso INI file. The Visual Server Administration Interface is available at this port and can be used to further configure the web server.

Web resources can be based on the file system, reside in the database or in WebDAV or any combination of all of them. WebDAV space can be specified at the path level, by default, paths beginning with /DAV are mapped to the WebDAV root collection (directory) and all other paths are assumed to be file system based. By default / is mapped to the directory specified as

ServerRoot in the HTTP Server section of the virtuoso.ini file.

Virtual Directories provide a way to make mappings from paths to other resources such as specific file system or WebDAV locations, other HTTP Servers acting as a proxy or to alter specific processing or authentication rules for a directory.

14.1. The HTTP Server

When a request comes in to one of the network interfaces where Virtuoso is listening for HTTP requests, it is matched against a set of virtual directory path mappings. A path mapping has the following attributes:

Interface - interface coming from HTTP request

Virtual Host - matched virtual host name

Logical Path - logical path

Mapped Path - physical location of the resource

Is in DAV - If the resource is placed in WebDAV domain

Default page - the name of the page to be returned if none is supplied

Browseable - allows for returning the list of files in a directory if no specific file is requested

Security - security restrictions to the resource

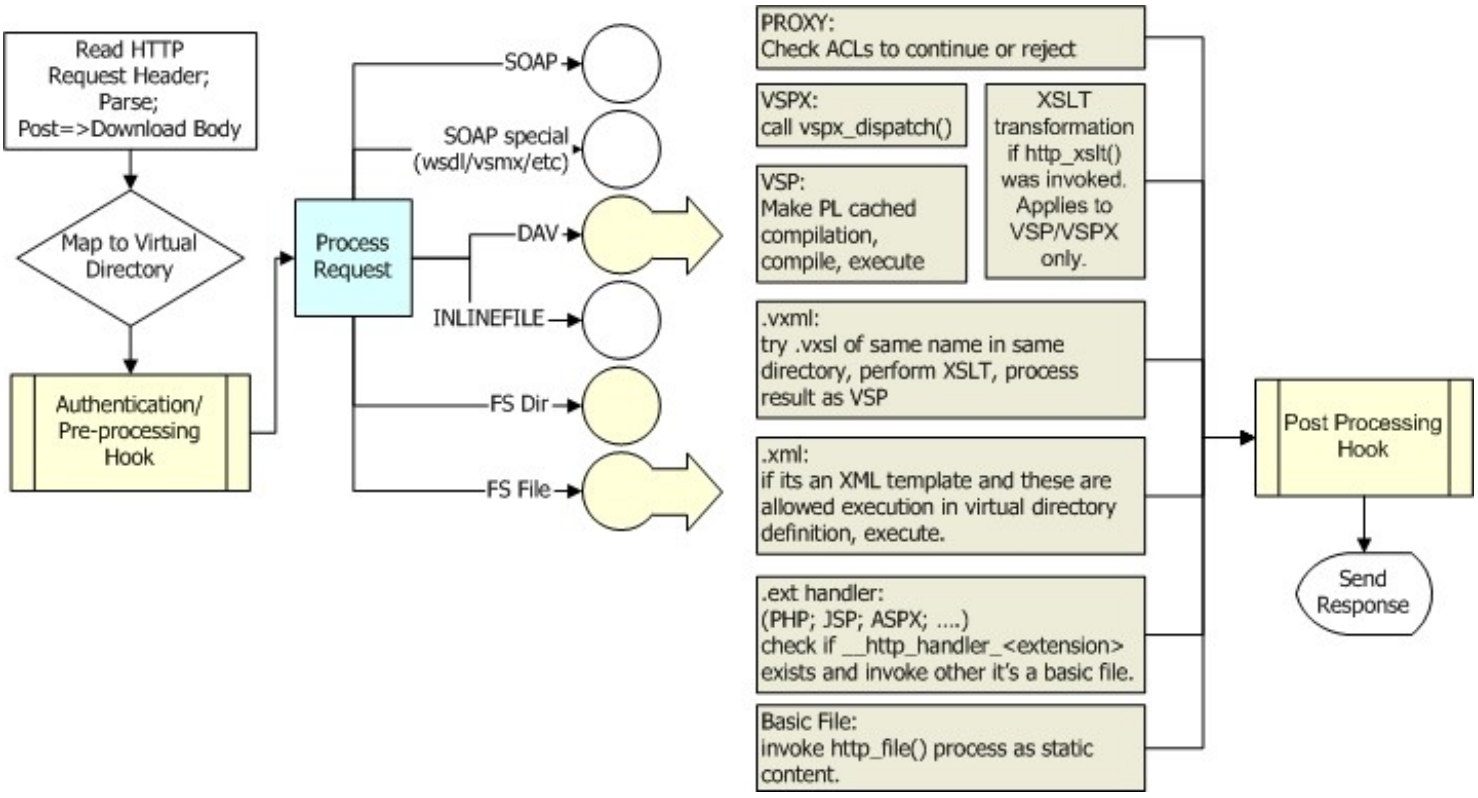
Authentication Function - Virtuoso/PL procedure name, which performs authentication

Realm - an string applied to Authentication function

Request Post-processing Function - Virtuoso/PL procedure name, which performs post-processing action, before sending the response

Database User Account - User account name, on behalf of which active content will be executed

Figure 14.1. HTTP Server Conceptual Diagram



Incoming requests are also checked against the HTTP access control lists. These lists rely on the following attributes of the connection to determine whether the request should be answered:

Client Host or IP Address - the incoming requestor is pattern matched to specify a range.

Destination Host or IP Address - Destination IP/Host match, also applicable to the proxy capabilities.

The Virtuoso HTTP server is HTTP/1.1 compliant. It can accept persistent connections from HTTP/1.1 clients. The HTTP/1.0

requests are processed as normal without the persistent connections feature.

Persistent HTTP connections offer several advantages, such as:

Reduced CPU usages by opening and closing fewer connections.

HTTP requests and responses can be pipelined on a connection. Pipelining allows a client to make multiple requests without waiting for each response, allowing a single TCP connection to be used much more efficiently with lower elapsed time.

Network traffic is reduced.

Latency on subsequent requests is reduced.

RFC2616 for more details

14.1.1. HTTP Server Base Configuration

The `[HTTPServer]` section of the Virtuoso INI file contains parameters that directly affect the HTTP server upon server startup. After the server has been started further configuration can be performed using the Visual Server Administration Interface. Here is an example of the section in the INI file:

```
[HTTPServer]
  ServerPort = 8890
  ServerRoot = ../vsp
  ServerThreads = 2
  MaxKeepAlives = 10
  KeepAliveTimeout = 10
  DavRoot = DAV
```

The meanings of these parameters are briefly explained here as a quick reference for the most frequently used parameters:

- **ServerPort.** This specifies the HTTP listen port for the VSP server.
- **ServerThreads.** This specifies the number of concurrently serviced HTTP requests. If there are more concurrent requests, accepting the connections will be deferred until there is a thread ready to serve each.
- **ServerRoot = ../vsp.** This is the file system path of the root directory of files served by the Virtuoso web server. The index.html in that directory will be served for the / URI. If relative, the path is interpreted relative to the server's working directory.
- **MaxKeepAlives = 10.** Connections by HTTP 1.1 clients can remain open after the initial response has been sent. This parameters sets a cap on how many socket descriptors will at most be taken by keep alive connections. Such connections will be dropped by the server ahead of timeout if this number would be exceeded. Thus the maximum number of open sockets for the Virtuoso HTTP server is this number plus the number of threads. A keep alive connection is by definition not associated to any pending processing on any thread.
- **KeepAliveTimeout = 10.** This is a timeout in seconds before Virtuoso closes an idle HTTP 1.1 connection.
- **DavRoot = DAV.** This specifies the root path of DAV resources. If DAV specific HTTP methods are used on Virtuoso, these should only reference resources with paths starting with this. This is the top level DAV collection. This is matched against URI's after the translation from external to internal URI's through the virtual directory table. See Virtual Directories below.

The Server Administration chapter contains a complete list of the Virtuoso INI file parameters. In particular, the [HTTPServer] section .

14.1.2. Virtual Directories

A Virtuoso virtual directory maps logical paths to physical resource locations accompanied by rules and/or parameters that govern how the mappings respond to user-agent (e.g. Web browser) requests. This mechanism allows physical locations to be obscured or simply reorganized. Some resource types require authentication challenges, such as the Visual Server Administration Interface, and/or special headers such as SOAP, which is another HTTP endpoint.

Virtual directories are useful when one server has to provide access to several Web sites. Redirects are not a universal solution to this, it is far better to define virtual directories that point to the other sites. Suppose that we have two companies, "a" and "b", that are to share a Virtuoso server but want to represented on the Web by `www.a.com` and `www.b.com` respectively. Their pages could be stored in directories "/a" and "/b" on the server, whilst virtual directories map requests appropriately:

```
http://www.a.com/  -->
```

```
/a
 http://www.b.com/  -->

/b
```

Hence, user-agent requests for `www.a.com` receive pages from /a, and likewise for "b". Requests under these domains are mapped back to their physical location such as the request for the URI `http://www.a.com/images/picture.jpg` retrieves the file `/a/images/picture.jpg` .

Virtual directory definitions are held within the system table DB.DBA.HTTP_PATH. Virtual directories can be administered in three basic ways:

Using the Visual Administration Interface via a Web browser.

Using the functions `vhost_define()` and `vhost_remove()` .

Updating the system table directory using SQL statements.

See Also:

Virtual Directory Administration UI

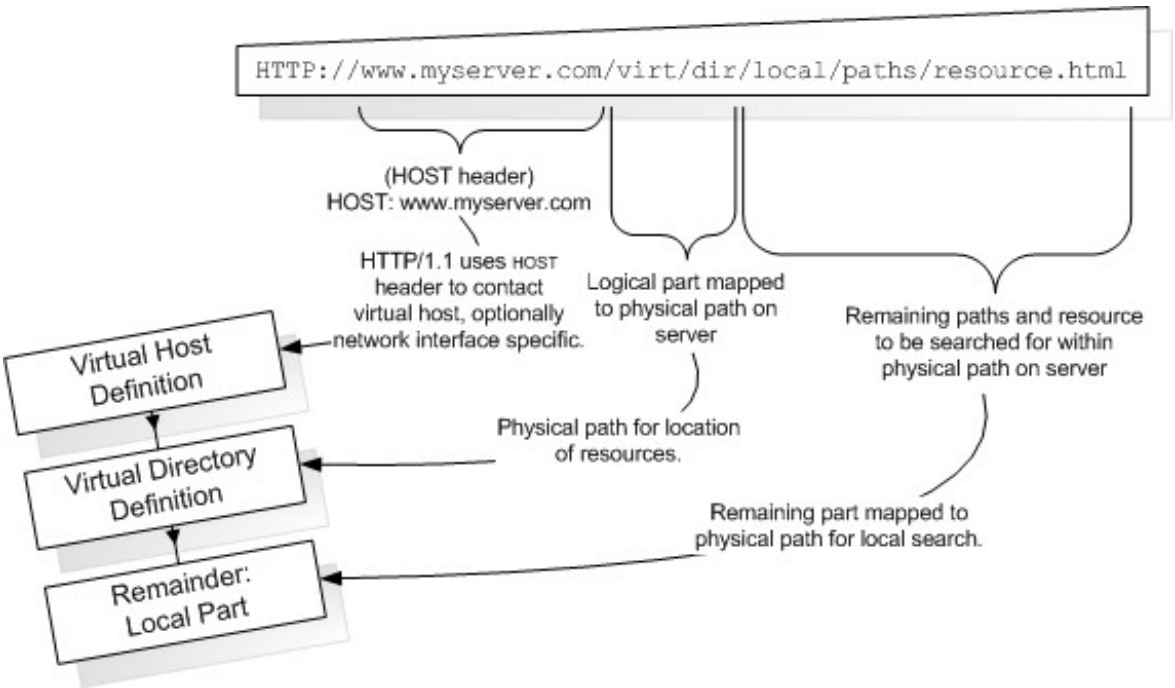
vhost_define() , vhost_remove()

HTTP_PATH system table

Virtuoso matches user-agent requests against a logical path using the longest entry that matches the path extracted from the URI. Suppose we have two entries '`/a/b` ' and '`/a` ' and a request is made of: '`http://foo.bar/a/b/c.html` ', will match the entry for '`/a/b` '.

First, Virtuoso will attempt to locate the physical path that has been mapped to a virtual host, interface and logical path. The virtual host corresponds to the 'Host' header field value from HTTP/1.1 requests. If the first step does not succeed then the server will try resolving the interface and logical path. Failing that, the default step will attempt to resolve the path directly to a physical location.

Figure 14.2. HTTP Virtual Directory Matching



Note:

HTTP 1.0 does not use the HOST header. Virtuoso will have little choice but to send HTTP 1.0 user-agents the contents of the default virtual host definition for the interface.

Thus if the following mappings are in effect:

```
/       ->  /DAV
/doc    ->  http://docs.biz.com:/
/admin  ->  /admin
```

The following translations would be made:

```
/doc/howto/intro.html      -> http://docs.biz.com:/howto/intro.html
/admin/help.vsp            -> /admin/help.vsp
/gizmo/doc.xml             -> /DAV/gizmo/doc.xml
```

Thus, the longest match is selected and the matching substring is replaced by the right hand side of the mapping. Note that this is also how automatic proxying takes place, since a physical path beginning with http:// will be passed forward to a remote server.

Default Pages And Directory Browsing

For each virtual host or logical path pair we can define a list of default pages. If the requested URL path is a directory then the server checks the default page definition for that virtual directory, if a default page exists then the path will be internally expanded to include its name, ands its contents returned.

Example 14.1. Default Page

if we have a mapping for the host:

```
www.a.com
```

with the logical path mapping of:

```
'/' mapped to '/a'
```

with default page 'index.htm', then if the URL

```
http://www.a.com/
```

is requested the server will try to send the content of '/a/index.htm'.

The same mechanism is used to determine whether a directory listing is to be returned. If a mapping is defined to have 'Browseable' set to a number greater than zero then the server, if a default page does not exist or is not defined, a directory listing will be returned to the calling client.

Virtual Hosting and Multi Hosting

The term Virtual Host refers to the practice of maintaining more than one server on one machine, differentiated by their apparent host name. It is often desirable for companies sharing a web server to have their own domains, with web servers accessible as www.company1.com and www.company2.com, without requiring the user to know any extra path information. The Virtual host can be IP-based or non-IP. The IP-based (Multi Hosting) refers to practice of having one machine listen for incoming requests on different network interfaces and respond with different pages. The non-IP-based (Virtual Hosting) refers to the practice of one machine having many DNS aliases, and requests from client to a specific alias returning a different response regarding content of 'Host' HTTP header field. Virtuoso supports IP-based, virtual IP-based, and name-based virtual hosts.

For distinct IP-based, hosts are used to determine on which interfaces Virtuoso will listen and accept HTTP requests.

Managing Host Metadata

To add metadata in /.well-known/host-meta, execute:

```
WS.WS.host_meta_add ([app-name], [xrd-xml-fragment])
```

For example:

```
WS.WS.host_meta_add
  (
```

```
    'dbpedia.page-descriptor',
    '<Link rel="http://dbpedia.org/resource-descriptor" template="http://dbpedia.org/page/{uri}"/>'
)
;
```

Virtuoso As A Proxy

The Virtuoso HTTP server can act as a proxy server on the same port as the HTTP port. You can put the host and port that the Virtuoso HTTP server is listening on, into your browser proxy settings and all requests will be processed by it. Also this can be used to retrieve a page inside VSP.

The physical path setting of a virtual directory definition can be URL to another HTTP server. In which case Virtuoso will act as a proxy to that site when the logical path for it is requested.

See Also:
Virtuoso also provides VSP functions for proxying.

`http_proxy()`.

The nature of Virtuoso's Web Proxying ability makes it easy and seamless to bind multiple websites under one roof. Existing sites do not have to move or change to be integrated under the Virtuoso Proxy. Simply map them under a logical path name. They can be mapped multiple times or from multiple ports.

If you already have pages written and working from other servers via ASP or PHP, then you will be able to run these servers concurrently with Virtuoso so they can share form data and give dynamic content from various sources, consistent with our value proposition of maximum incorporation of new technologies with minimum disruption to existing infrastructure. Whether these servers were hosted on various machines or the same machine there is no need to expose their running ports and services. This makes the end user experience cleaner, and helps maintain some server security and/or anonymity.

Note:
Virtuoso provides runtime hosting capabilities and PHP support, therefore ASP.Net and PHP and other applications can be run and hosted directly within the file system or WebDAV.

Suppose that you have two machines running existing web servers that serve various parts of your intranet. One web server may have been constructed for or by your sales department while the other server may have been a built by the support department. These servers could be resolved by http://sales.mycompany.com/ and http://support.mycompany.com/ respectively.

You can place Virtuoso on another server and start integrating your existing sites under this installation. You may use the Visual Server Administration Interface or choose to use the following commands via the isql interface:

```
DB.DBA.VHOST_DEFINE(lpath=>'/sales', ppath=>'http://sales.mycompany.com/');
DB.DBA.VHOST_DEFINE(lpath=>'/support', ppath=>'http://support.mycompany.com/');
```

This way your old servers will exist under /sales/ and /support/ of your new server. Now you can start adding virtuoso .vsp pages to your new Virtuoso server and they operate interleaved with your existing pages to add new life and functionality as required.

You may decide that you want to install Virtuoso onto a server where a web server already exists. If you plan to use Virtuoso as your default web server and the proxy to your existing server then you will need to make sure that the servers run on different ports. The default port is 80, you will have to configure Virtuoso to use this port from the virtuoso.ini file and then move your existing web server port to another number. Afterwards the procedure is similar:

```
DB.DBA.VHOST_DEFINE(lpath=>'/apache', ppath=>'http://example.com:90/');
```

Proxying Virtuoso via Apache

You may also achieve the same goal as above but in reverse, using another web server as a proxy in front of Virtuoso. If you have an existing Apache server that you want to keep as you default web server then you can set up a proxy within Apache to Virtuoso.

Firstly you will need to make sure that Apache can make use of the mod_proxy module available from most Apache distribution sites. You then have to make sure that it is referenced in your httpd.conf (or apache.conf) file. You should have something like:

```
...
LoadModule proxy_module       modules/libproxy.so
```

```
...
AddModule mod_proxy.c
...
```

Configuration steps

Below we will use the <Location> directive to simplify the configuration:

```
<Location /virtuoso/>
   ProxyPass               http://example.com:8890/
   ProxyPassReverse        /
</Location>
```

1. Set the ProxyPass directive:

   The ProxyPass directive makes Apache to change all incoming URLs and map it to the internal http endpoint.

   So when the browser makes a request for:

   ```
   http://example.com/virtuoso/conductor/login.vsp
   ```

   it is rewritten to use:

   ```
   http://example.com:8890/conductor/login.vsp
   ```

   before sending the request over to the Virtuoso server.
2. Set the ProxyPassReverse directive:

   The ProxyPassReverse directive rewrites the HTTP Headers that come back from Virtuoso to map back to the external URL. This is needed for e.g. 303 Location redirects where Virtuoso will use:

   ```
   Location: http://example.com:8890/conductor/pageXXX.vsp
   ```

   which Apache needs to rewrite to:

   ```
   Location: http://example.com/virtuoso/conductor/pageXXX.vsp
   ```

   before sending the reply back to the browser.
3. If the mapping is / ---> / instead of /virtuoso/ ---> / then the settings should be done, since ProxyPass and ProxyPassReverse only deal with rewriting urls and http headers.

   When however there is a path mapping, there is a third step to take:

   Pages can contain clickable links like:

   ```
   <a href="/conductor/mypage.vsp">Click Here</a>
   ```

   If you click on this link in your browser, it would use:

   ```
   http://example.com/conductor/mypage.vsp
   ```

   which does not map back to your /virtuoso/ vpath in apache.

   As phpBB3 has been written from outset to cater for this situation, it will always need to recalculate fully qualified host/path names everywhere in its pages, which is not always very practical.

   Thus Apache needs to be configured to do page rewriting as well as in:

   ```
   ProxyHTMLEnable         On
   ProxyHTMLURLMap         / /virtuoso/
   ProxyHTMLURLMap         http://example.com:8890/ /virtuoso/
   ```

   This will rewrite the content of every page to make sure that links inside the page are rewritten to use the external mapping of this instance.

If you have set Virtuoso to use `EnabledGzipContent=1` , then you need to tell apache it may need to gunzip the content before doing this rewrite with the following line:

```
            SetOutputFilter         INFLATE;DEFLATE
```

Although this takes a bit extra CPU power etc, it is still practical to setup a virtual path on user's own system that points to some external system.

For example, add this to your httpd.conf to get a mapping to dbpedia-live instance:

```
       <Location /dbp/>
            ProxyPass               http://dbpedia-live.openlinksw.com/
            ProxyPassReverse        /
            ProxyHTMLURLMap         / /dbp/
            ProxyHTMLURLMap         http://dbpedia-live.openlinksw.com/ /dbp/
            SetOutputFilter         INFLATE;DEFLATE
       </Location>
```

Now you should be able to use for ex.:

```
       http://example.com/dbp/page/London
```

Usage Example

```
NameVirtualHost 82.191.21.32

<VirtualHost 82.191.21.32>
ServerName www.mysite.net <http://www.mysite.net>
...

     #  Disable global proxy
     ProxyRequests       Off

     #  Pass original host to Virtuoso
     ProxyPreserveHost   On

     #  Timeout waiting for Virtuoso
     ProxyTimeout        300

     #  Set permission
     <Proxy *>
         Order deny,allow
         Allow from all
     </Proxy>

     #
     #  Map /virtuoso/ to a local Virtuoso instance.
     #
     #  Since ProxyPass and ProxyPassReverse only fix the Headers
     #  of the request, we need to use ProxyHTMLURLMap to rewrite
     #  content.
     #
     <Location /virtuoso/>
         ProxyPass               http://example.com:8890/
         ProxyPassReverse        /

         #  Enable rewrite rules
         ProxyHTMLEnable         On
         ProxyHTMLURLMap         / /virtuoso/
         ProxyHTMLURLMap         http://example.com:8890/ /virtuoso/

# Uncomment this when EnabledGzipContent=1 in virtuoso.ini
         #SetOutputFilter         INFLATE;DEFLATE
     </Location>
</VirtualHost>
```

If we map the virtual host straight through to Virtuoso, we only need header rewriting and save the time/cpu power to rewrite the content:

```
     #
```

```
#  Map / to a local Virtuoso instance
#
#  Since paths are mapped straight through, we do not have to
#  rewrite the content.
#
<Location />
    ProxyPass               http://example.com:8890/
    ProxyPassReverse        /
</Location>
```

14.1.3. Authentication

If a Virtuoso/PL procedure is specified to perform authentication for this mapping then it will be executed. The procedure can take one (varchar) parameter, the 'Realm' value. The result from the procedure must be 1 if authentication successful otherwise must be zero (0). If the procedure returns 0 this causes the processing to terminate and whatever output the hook generated to be sent to the client. Typically this will be an authentication challenge.

14.1.4. Session Management

The Virtuoso HTTP session management consists of functions for session variables manipulation and an ability to define a pre- and post-processing function. The pre and post-processing functions are used to save and restore session data between HTTP posts, usually to and from a session table.

Session management must be enable by settings the flag for persistent session variables in virtual directory mapping. Virtual directory mappings use the *persistent_session_variables* flag, which when specified, session variables can be used in a post-process function to determine if the session variables content must be stored on to the session table or not.

The post-processing function hook can be any user-defined Virtuoso/PL procedure, it will be executed every time after processing of the active page.

VSP Session Management and Session Variables

14.1.5. Writing Your Own Authentication and Session Handling

We will explain the following precompiled procedures in Virtuoso used to authenticate three branches of users.

HP_AUTH_SQL_USER - VSP authentication based on DB users
HP_AUTH_DAV_ADMIN - VSP authentication based on WebDAV users
HP_AUTH_DAV_PROTOCOL - WebDAV repository authentication

```
-- Authenticate against names and passwords in SYS_USERS, using HP_SECURITY for level

create procedure
DB.DBA.HP_AUTH_SQL_USER (in realm varchar)
{
  declare _u_name, _u_password varchar;
  declare _u_group, _u_id, allow_basic integer;

  declare auth, sec, lev varchar;
  declare _user varchar;
  declare ses_dta, lines any;

  lines := http_request_header ();         -- got a request header lines
  sec := http_map_get ('security_level');  -- got a security level from http mapping
  if (isstring (sec))
    sec := ucase (sec);
  if (sec = 'DIGEST')
    allow_basic := 0;   -- if security is only digest then allow basic is false
  else
    allow_basic := 1;

  auth :=
    DB.DBA.vsp_auth_vec (lines);        -- parse request header to got authentication credentials
```

```
  if (0 <> auth)                          -- and if client sent any authentication information try it
    {

     lev := get_keyword ('authtype', auth, ''); -- check if client tried basic but
                                                -- domain restricted to digest only
     if (allow_basic = 0 and 'basic' = lev)
        goto nf;
      _user := get_keyword ('username', auth, '');

      if ('' = _user) -- if no user name then 'bye'
        return 0;

      whenever not found goto nf;  -- if no such user in table - 'bye'

      -- got the password from users table

      select U_NAME, PWD_MAGIC_CALC (U_NAME, U_PASSWORD, 1), U_GROUP, U_ID
        into _u_name, _u_password, _u_group, _u_id from DB.DBA.SYS_USERS
        where u_name = _user;

      -- check credential against user name and password

      if (0 = _u_group and 1 = DB.DBA.vsp_auth_verify_pass (auth, _u_name,

          update DB.DBA.ADMIN_SESSION set ASES_VARS = serialize (vars) where ASES_ID = sid;
      }
  }
  ;
```

These functions are implemented as part of Virtuoso server by default. The user can freely define their own procedures based on this logic to use for special authentication (different users information table etc.) and session management.

14.1.6. Cancellation of Web Requests

If there are many long-running tasks processing on Virtuoso it is possible to have denial of service. To prevent this we can use status and stop functions. We can retrieve the URL, client IP-address, and process status code for all currently running VSP requests, then use this information to isolated and eliminate a process.

`http_pending_req()`

Long HTTP Transactions

14.1.7. Virtuoso WebRobot API

The Virtuoso WebRobot (WebCopy) is useful for retrieving Internet web sites and storing them on to a local WebDAV repository. Once retrieved, the local copy in the WebDAV repository can be exported to the local filesystem or another WebDAV enabled server. The common features and usages are demonstrated in the WebCopy User Interface in the Visual Server Administration Interface. This document provides the actual API's and techniques useful for some other implementations.

Creating A New Target

A new web server target is created by inserting a row in to the WS.WS.VFS_SITE table and then a row in to the WS.WS.VFS_QUEUE table.

See Also:
Web Robot System Tables for table definitions

Example 14.2. Creating a new target

This example creates a new target pointing to the site http://www.foo.com/help/, with instructions to walk across foreign links, delete a local page if it is detected that it has been removed from the remote, retrieve images, walk on entire site using HTTP GET method. The content will be stored in /DAV/sites/www_foo_com collection in the local WebDAV repository.

1. Create target for http://www.foo.com/help/

```
insert into WS.WS.VFS_SITE
    (VS_DESCR,VS_HOST,VS_URL,VS_OWN,VS_ROOT,VS_NEWER,VS_DEL,
      VS_FOLLOW,VS_NFOLLOW,VS_SRC,VS_OPTIONS,VS_METHOD,VS_OTHER)
  values
    ('My first test', 'www.foo.com', '/help/', 1, 'sites/www_foo_com', '1990-01-01',
      'checked', '/%;', '', 'checked', null, null, 'checked');
```

2. Create start queue entry

```
insert into WS.WS.VFS_QUEUE
    (VQ_HOST,VQ_TS,VQ_URL,VQ_ROOT,VQ_STAT,VQ_OTHER)
  values ('www.foo.com', now(), '/help/', 'sites/www_foo_com', 'waiting', null);
```

Creating A Custom Queue Hook

The custom queue hook can be used to extract the next entry from the robot's queue following a custom algorithm. The following example extracts the oldest entry comparing to the my_data array (this array consists of non-desirable sites) and returns if some are found.

Example 14.3. Creating A Custom Robot Queue Hook

```
create procedure
  DB.DBA.my_hook (
    in host varchar, in collection varchar, out url varchar, in my_data any
  )
{
  declare next_url varchar;
  whenever not found goto done;

  -- we trying to extract the oldest entry
  declare cr cursor for select VQ_URL from WS.WS.VFS_QUEUE
      where VQ_HOST = host and VQ_ROOT = collection and VQ_STAT = 'waiting'
      order by VQ_HOST, VQ_ROOT, VQ_TS for update;

  open cr;
  while (1)
  {
    fetch cr into next_url;
    if (get_keyword (host, my_data, null) is not null) -- process if host not in black-list
    {
      update WS.WS.VFS_QUEUE set VQ_STAT = 'pending'
          where VQ_HOST = host and VQ_ROOT = collection and VQ_URL = next_url;
      url := next_url;
      close cr;
      return 1;
    }
    else -- otherwise continue finding
        update WS.WS.VFS_QUEUE set VQ_STAT = 'retrieved'
          where VQ_HOST = host and VQ_ROOT = collection and VQ_URL = next_url;
    }
done:
  -- if we arrive at the bottom of the queue return false to stop processing
  close cr;
  return 0;
}
;
```

Note:

The default function will return the oldest entry from queue without any restriction. The follow/not-follow restrictions are applied to the path on target before inserting a new queue entry.

Starting The Site's Retrieval/Update

The site retrieval can be performed with the WS.WS.SERV_QUEUE_TOP PL function integrated in to the Virtuoso server.

```
serv_queue_top()
```

Exporting Local Content To Filesystem Or Other Webdav Enabled Server

```
lfs_exp
```

```
dav_exp
```

14.1.8. HTTP Server Extensions

The Virtuoso shared object library enables you to create your own custom extensions to the Virtuoso HTTP server and create custom VSEs. Support for PHP page execution was implemented using this functionality. Virtuoso can automatically switch processing mode from VSP to PHP or some other custom extension based on the extension of the files being requested from the HTTP server. To enable Virtuoso to process files of a different extension you have to write a VSE handler where part of the name contains the extension: *__http_handler_[extension]* . The VSEs for HTTP handling must have the following parameters:

```
__http_handler_<extension> (  in resource varchar,
                              in parameters vector,
                              in request_header vector,
                              inout type_flag any);
```

- *resource* is either the path to a file or the content of a resource in the WebDAV store. The interpretation of this parameter by the server is dependent of the type_flag parameter.
- *parameters* for execution, the server will pass to this parameter a string session containing the entity body of the POST method request.
- *request_header* is the HTTP request header lines as an array of strings. This parameter will accept the original header as a vector. The vector will contain the complete HTTP request header.
- *type_flag* is an in/out parameter which is a flag for indicating the type of the first parameter. If the resource parameter is a file path in the file system this flag should be NULL, if the resource is located in the WebDAV store this flag should be set to URI of the WebDAV resource, something like: virt://WS.WS.SYS_DAV_RES.RES_FULL_PATH.RES_CONTENT:/DAV/dir1/subdir/myfile.php. Virtuoso will return in this parameter an array of two strings set to the http response status line and the header after execution.

Virtuoso Server Extensions Interface

14.1.9. Chunked Transfer Encoding

Virtuoso supports HTTP 1.1 Chunking Encoding which allows Virtuoso to send the user agent chunks of output as the page is still processing. Chunking is enabled by calling `http_flush(1)` within the VSP page. Chunks are sent for every 4k worth of output generated. Chunked mode requires the following conditions:

no "Content-Length" header sent to the client using http_header()

no "Content-Encoding" header sent to the client using http_header()

use http_xslt() is not permitted

The client supports HTTP 1.1

Failing these conditions, `http_flush(1)` will be a No-Operation.

Chunked mode is not supported for static content.

RFC-2616

14.1.10. Using Virtuoso Server capabilities via Apache Web Server

In some situations Virtuoso services like WebDAV, JSP, PHP etc. may need to be accessed via an Apache Web Server. All this can be done through apache's mod_proxy to Virtuoso HTTP server and the Virtuoso HTTP server can be configured to take requests coming only from localhost.

The following configuration makes : The Virtuoso server to listen for HTTP requests coming ONLY from localhost. Apache proxies the outside requests to Virtuoso HTTP server.

```
line added to the /etc/httpd/conf/httpd.conf
(999.999.999.999, must be changed with actual IP address of external interface):
-----------------------------------
Listen 8080
<VirtualHost 999.999.999.999:8080 127.0.0.1:8080>
       ServerAdmin webmaster@host.example.domain
       ProxyPass  / http://example.com/
</VirtualHost>
-----------------------------------

Then changes in the virtuoso.ini

[HTTPServer] section)
...
ServerPort = 127.0.0.1:6666
...
```

14.1.11. Setting Up the Virtuoso HTTPS Listener

The Setting up of the Virtuoso HTTPS Listener can be done by using the file system or using the Virtuoso conductor.

Note that when you want to change from Virtuoso hosted Cert and Public Key to File System and vice versa, first should be stopped the listener for either setup.

Setting Up the Virtuoso HTTPS Listener to host Certificate and Public Key using File System

1. X.509 certificate Generation

   The WebID Protocol consumer needs an x509 certificate with v3 extension "Subject Alternate Name". This attribute is used for the owner's Web ID. For testing purposes we used OpenSSL demo CA to generate such certificates. If you are not using the OpenSSL demo CA, you must first setup a self-signed CA; read OpenSSL documents on how to do this.

   a. Add the following line to the `[usr_cert]` section of the `openssl.cnf` file:

      ```
      subjectAltName=$ENV::ALTNAME
      ```

   b. Set the environment variable `ALTNAME` to the owner's Web ID, e.g.,

      ```
      export ALTNAME=URI:http://example.com/dataspace/person/myname#this
      ```

   c. Make a self-signed certificate, e.g.,

      ```
      $ CA.pl -newreq (follow the dialog)
      $ CA.pl -sign
      ```

   d. When asked to commit the certificate, make sure you see several lines above, like

      ```
      X509v3 Subject Alternative Name:
          URI:http://example.com/dataspace/person/myname#this
      ```

   e. If your browser wants a `PKCS#12` bundle, you must make one

      ```
      $ openssl pkcs12 -export -in newcert.pem -inkey newkey.pem -out mycert.p12
      ```

f. Rename `newcert.pem` and `newkey.pem`, to `mycert.pem` and `mykey.pem` for example.

2. Move `newcert.pem`, `newkey.pem`, and `cacert.pem` into the server's working directory. In our test case, we put the keys in a '`keys`' sub-directory, and added the following lines to the `[HTTPServer]` section of the Virtuoso INI file, `virtuoso.ini`:

```
SSLPort                     = 4443
SSLCertificate              = ./keys/localhost.cert.pem
SSLPrivateKey               = ./keys/localhost.key.pem
X509ClientVerifyCAFile      = ./keys/localhost.ca.pem
X509ClientVerify            = 1
X509ClientVerifyDepth       = 15
```

3. Also in the Virtuoso INI file, in the `[URIQA]` section, `DefaultHost` (`example.com:8890` below) must be edited to correspond to the DNS-resolvable host name ("CNAME") of the Virtuoso host, combined with the `ServerPort` as set in the `[HTTPServer]` section of the same INI file.

```
[URIQA]
DynamicLocal = 1
DefaultHost  = example.com:8890
```

For example, if the CNAME of the host is `virtuoso.example.com`, and the `ServerPort` is `4321`, the `DefaultHost` should be set to `virtuoso.example.com:4321`

```
[URIQA]
DynamicLocal = 1
DefaultHost  = virtuoso.example.com:4321
```

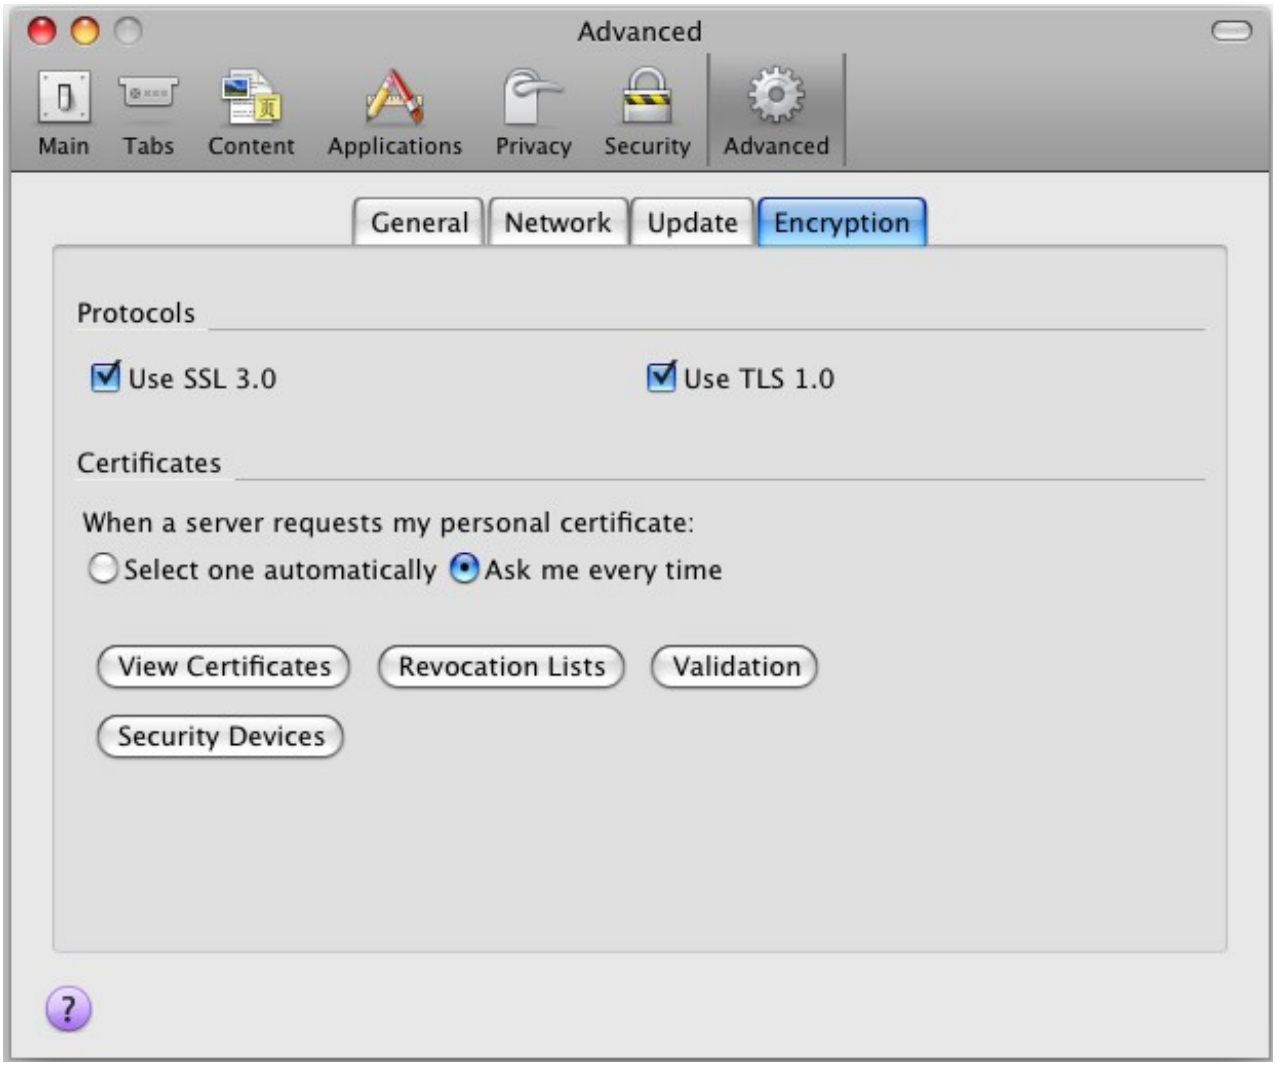
4. Start the Virtuoso server, and look at the log file. Once HTTPS is up, you should see something like:

```
HTTPS Using X509 Client CA ....
HTTPS/X509 server online at 4443
```

5. Setting Up Firefox:

a. In the Preferences dialog, open the Advanced tab, and click the "View certificates" button.

Figure 14.3. HTTPS Listener



b. Click the "Add exception" button ,and enter the address of the HTTPS server you've just configured, i.e. https://virtuoso.example.com:4443/
c. Click OK, and confirm the exception.

Figure 14.4. HTTPS Listener

d. Click to the "Your Certificates" tab, and import `mycert.p12` .

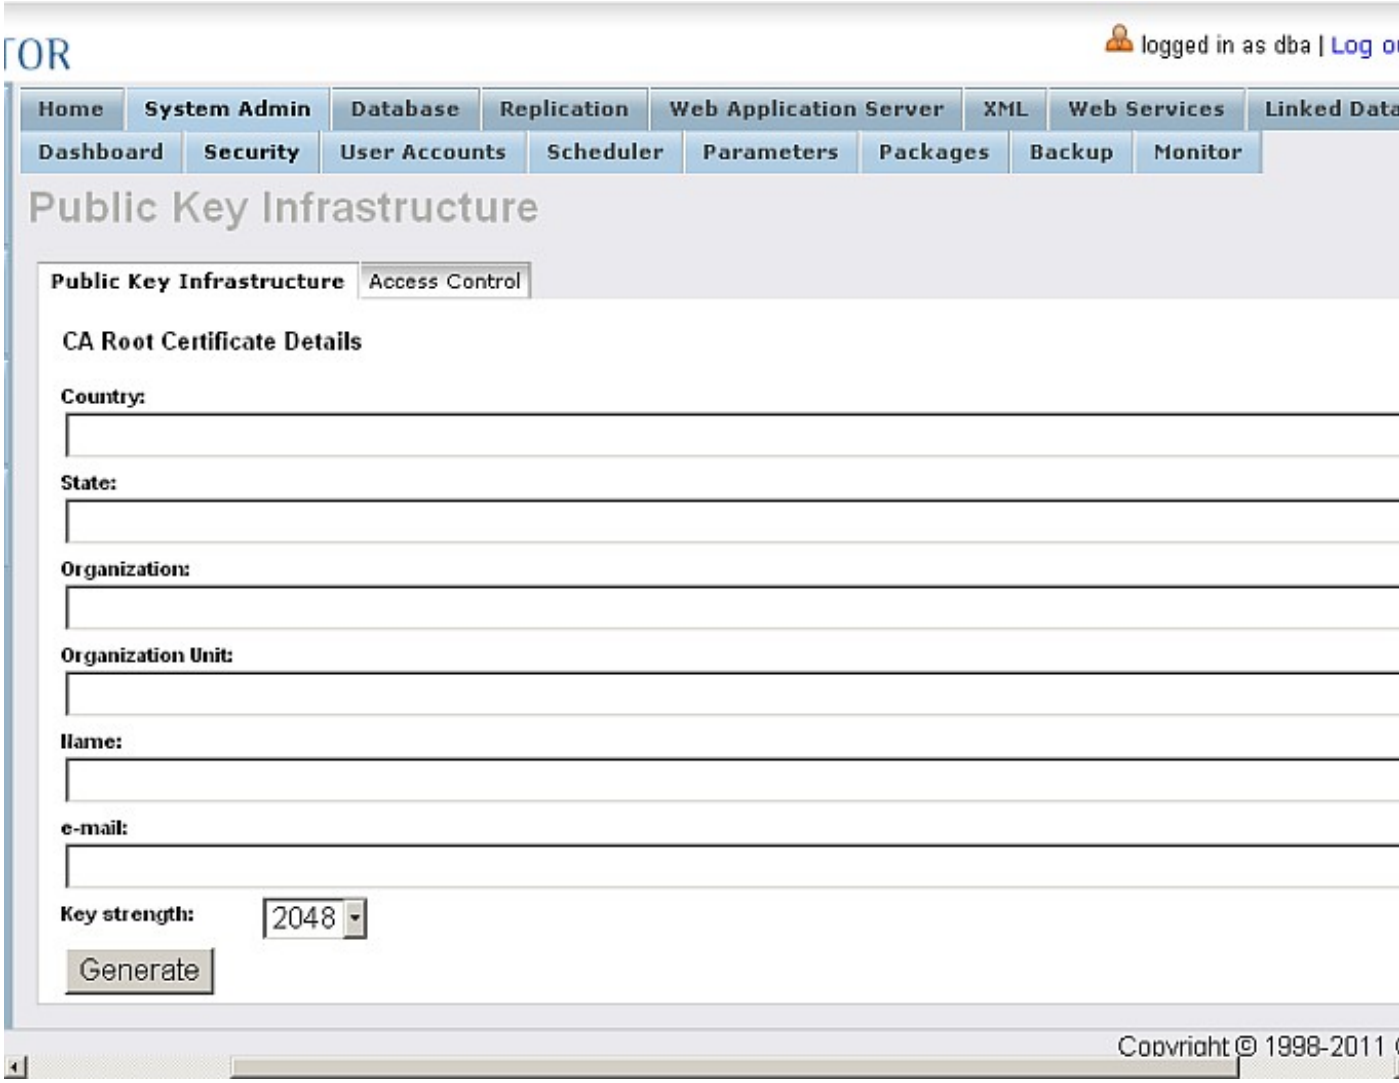
Setting Up the Virtuoso HTTPS Listener to host Certificate and Public Key using Virtuoso Conductor

1. Go to the `http://cname:port/conductor` URL, enter the DBA user credentials.

Figure 14.5. HTTPS Listener

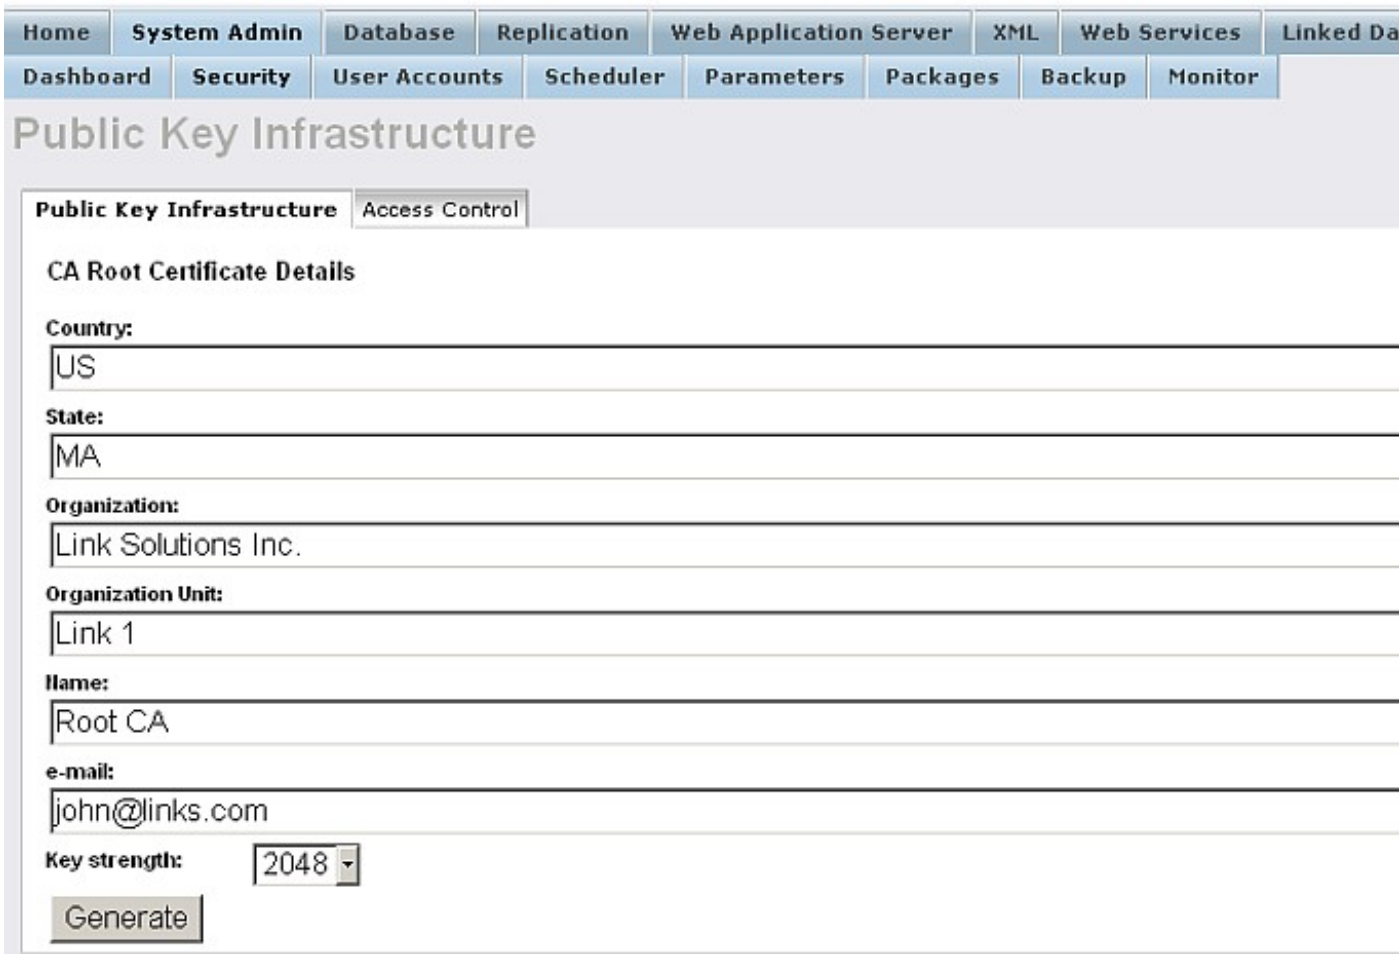
2. Go to System Admin->Security

Figure 14.6. HTTPS Listener



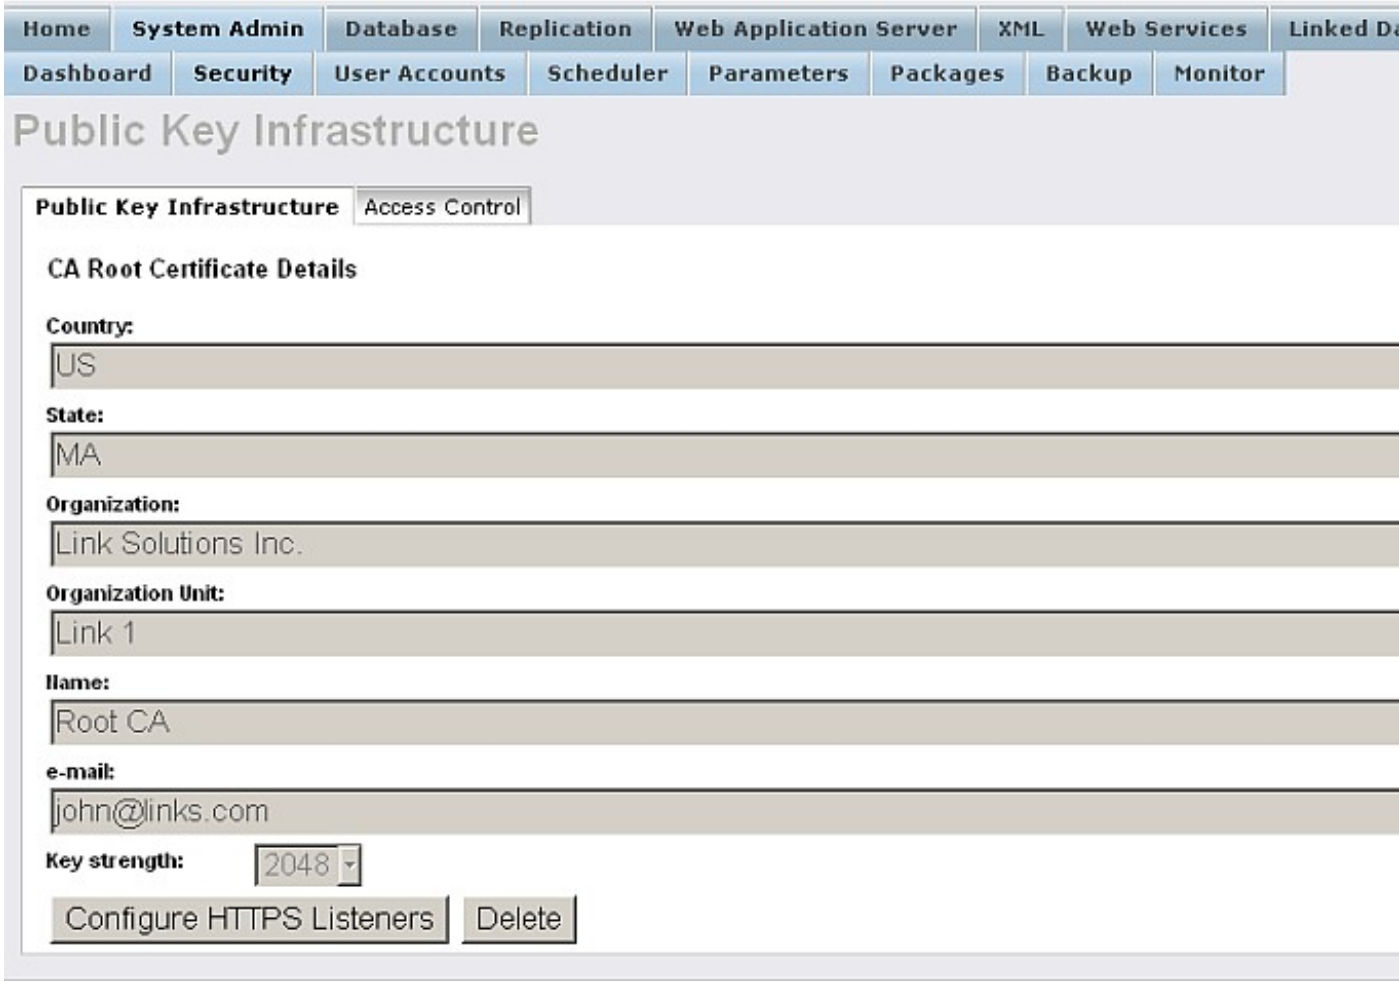
3. Enter the Issuer details:

Figure 14.7. HTTPS Listener



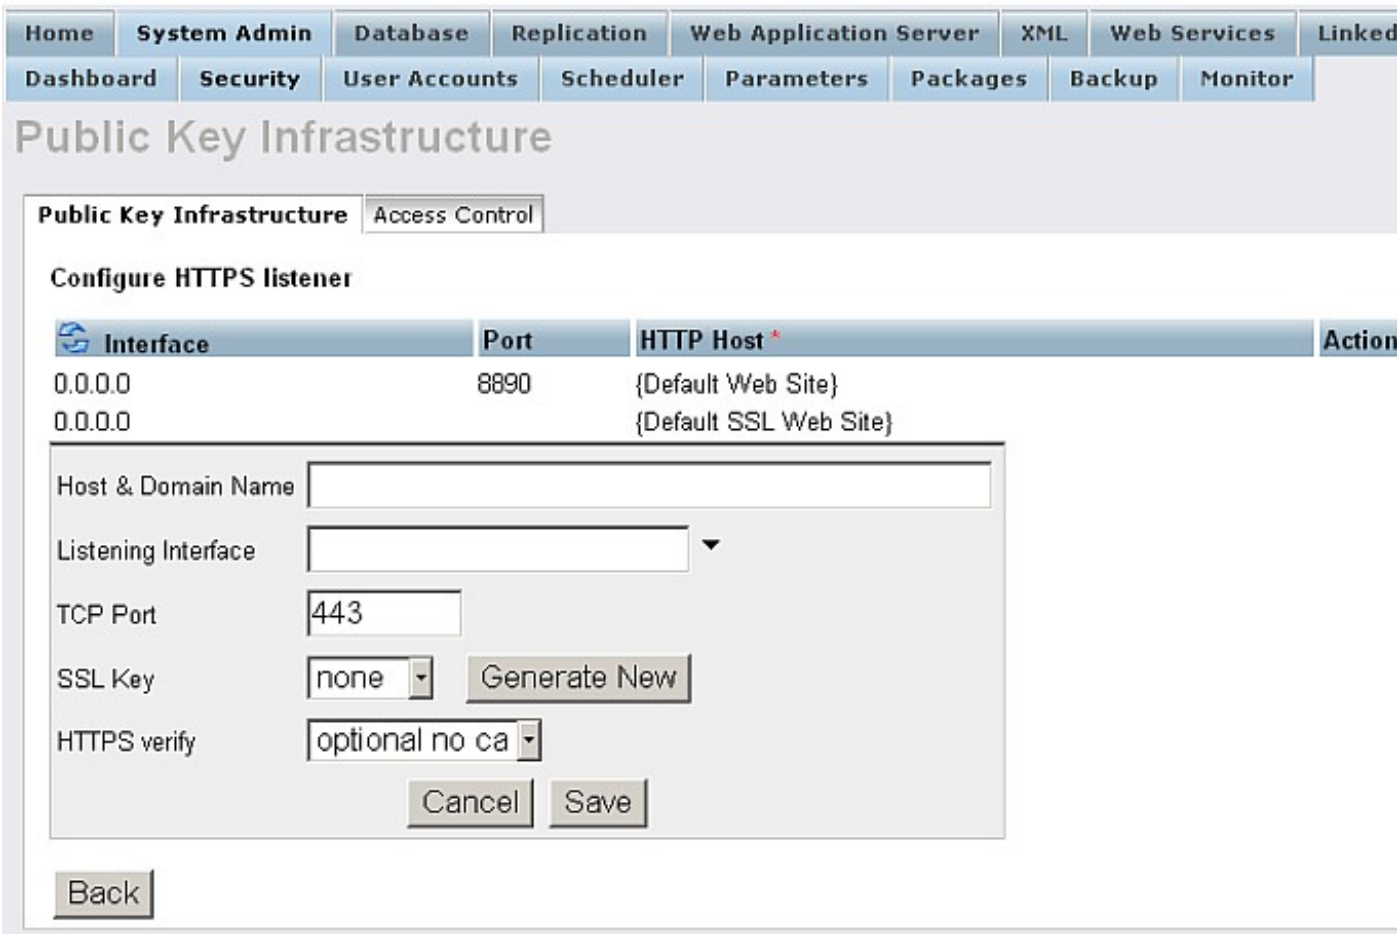
4. Click Generate

Figure 14.8. HTTPS Listener



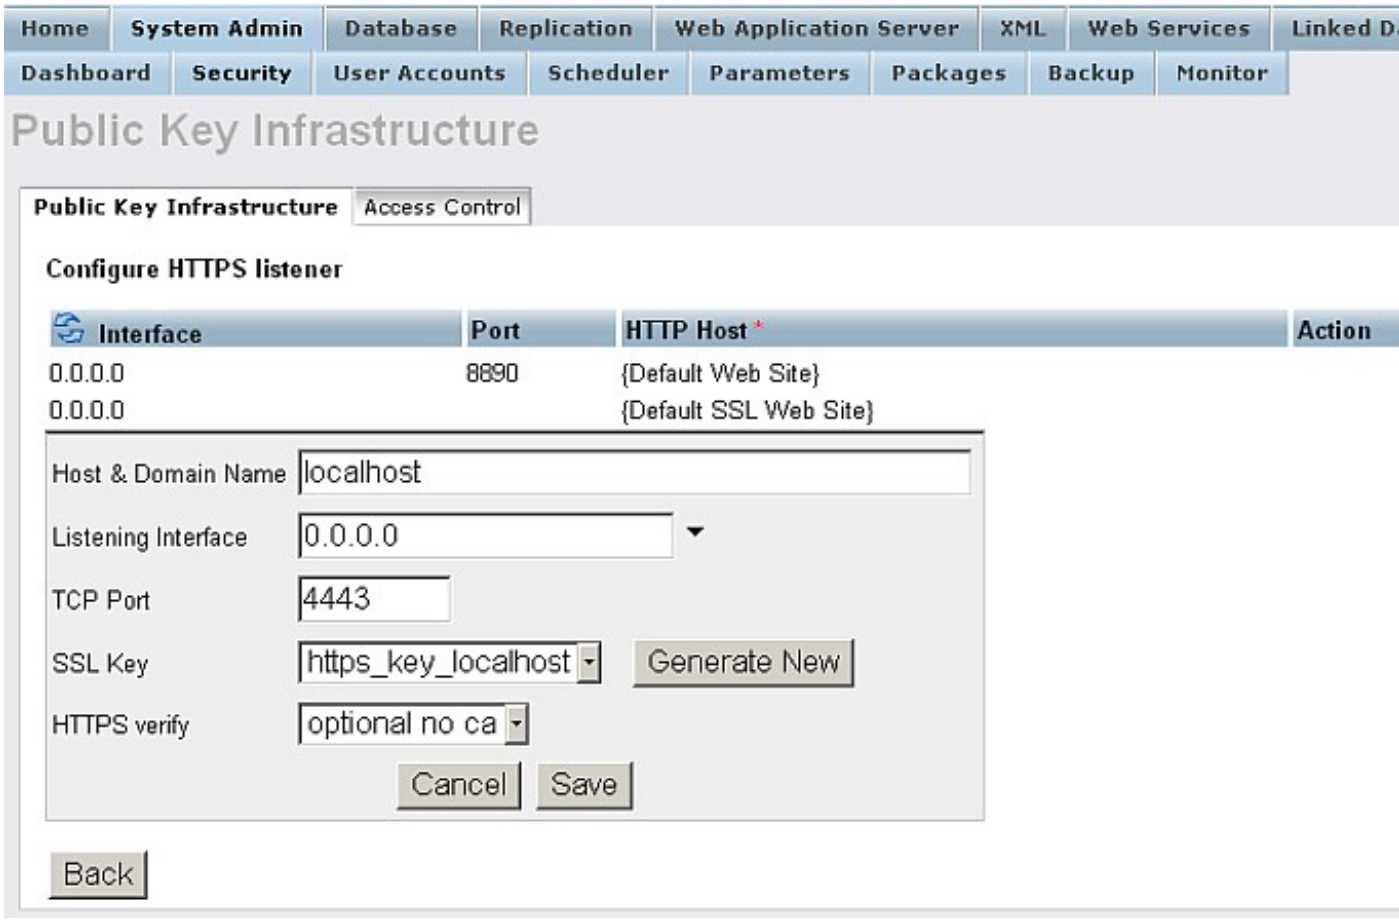
5. Click Configure HTTPS Listeners

Figure 14.9. HTTPS Listener



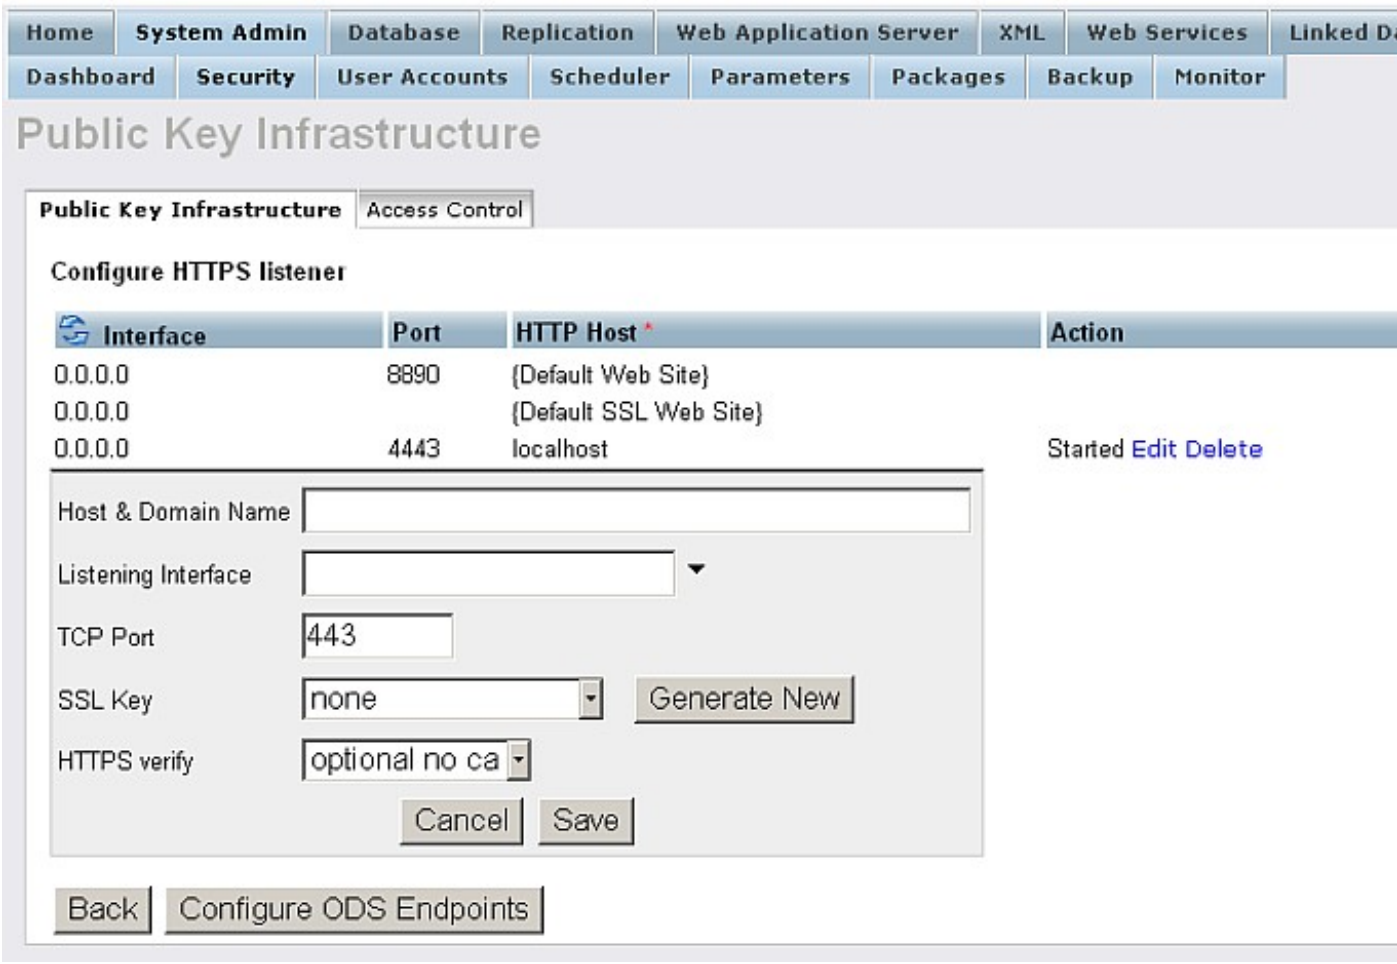
6. Edit the new listener, and click "Generate New" key.

Figure 14.10. HTTPS Listener



7. Click Save

Figure 14.11. HTTPS Listener



8. Setting Up Firefox:

   a. In the Preferences dialog, open the Advanced tab, and click the "View certificates" button.
   b. Click the "Add exception" button and enter the address of the HTTPS server you've just configured, i.e. https://virtuoso.example.com:443/
   c. Click OK, and confirm the exception.

Figure 14.12. HTTPS Listener

14.2. Web Services ACL (Access Control List)

Virtuoso provides a generic access control list for HTTP and other Internet protocol clients. This mechanism uses wildcard expressions to selectively block and allow ranges of IP addresses. An ordered set of patterns is matched against the origin of the request. The first matching pattern's allow/deny flag determines whether the client is approved or not.

The patterns for designating a range of IP addresses follow the syntax of the SQL 'LIKE' predicate; i.e. '%.foo.bar' or '*.foo.bar' for example.

See Also:
The LIKE Predicate & Search Patterns section.

The following mechanisms for services access restriction are defined by default:

Web Server ACL - controls access to the Web server (basic fire wall)
Web Proxy server ACL - controls access to the Web proxy server
News Server ACL - controls access to the Internet news groups (reading or posting)

14.2.1. General purpose ACLs

The system table `DB.DBA.HTTP_ACL` is used to persist ACL definitions, which can be managed with simple INSERT/UPDATE/DELETE statements. The table has the following layout:

Columns for DB.DBA.HTTP_ACL:

HA_LIST - ACL name
HA_ORDER - Position in the list
HA_OBJECT - Object ID (applicable to news groups also)

HA_CLIENT_IP - *PATTERN*

HA_FLAG - Allow/Deny flag, 0 - allow, 1 - deny

HA_RW - Read/Write flag, 0 - read, 1 - post

HA_DEST_IP - Destination IP/Host (applicable to the proxy also)

HA_RATE - Rate Limit

The primary key covers columns HA_LIST, HA_ORDER, HA_CLIENT_IP and HA_FLAG.

See Also

The full schema is listed in the Appendix under System Tables .

HA_LIST (required). Name of the ACL, This is a label to designate a group of rules applicable to a specific service. There are three pre-defined groups which are: HTTP, NEWS, PROXY. Please note that name of group is treated as case-insensitive string. In other words we can think about HA_LIST as domain of the ACL. Developers can use that table to add their own ACLs , and use them with API functions which are discussed in the next section.

HA_ORDER (required). Ordinal number of the rule within its list. This number should be unique within a specific group to have a well defined order of rule matching. Please note that if order is equal the one with allow flag equal to zero (HA_FLAG value see below) takes precedence. The order for applying rules for particular list is in ascending order i.e. first will be applied the rule with the smallest value of HA_ORDER.

HA_CLIENT_IP (required). A pattern to designate separate IP address or group of addresses. This is a string value as for 'LIKE' operator. Some example is: 192.168.*; will match all hosts from local private network.

HA_FLAG (required). A boolean; zero or positive number designating a rule to be applied for matching address/host. The default option is zero (false) for allowed action; positive (true) for denied action. So application may use it in reverse; but in that case it needs to take in account the order precedence (see HA_ORDER).

HA_OBJECT (optional). An integer designating an ID used in predefined ACL for Internet News groups to designate ID of the group. This can be used also in other applications where one desires to apply different rules for different objects. We can think of it as a sub list inside an ACL.

HA_RW (optional). An integer designating a action to be restricted (read/write); used in predefined Internet News groups ACL.

HA_DEST_IP (optional). A string containing pattern to match another IP number; this is used in Web Proxy server ACL. This can also be used in custom application logic.

HA_RATE (optional). An float for Rate Limit. The filter calculates hit rate average and compares with limit for http acl rule. If it is larger then will drop connection. Once per day the statistics will be reset.

- Regular expressions are not supported.
- Can be used patterns, for ex:

```
-- like '%something' or
-- something*
```

The Rate Limit UI can be configured from Conductor->System Admin->Security->Access Control where:

Rate limit is hits/per second from one IP address.

For search engine optimization statistics, for example can be set rate limit 10 (or even 100 so to start to collect statistics), and then to check with http_acl_stats () what values are returned.

14.2.2. ACL Definition/Removal

ACL's can be managed from the administration web interface using the following steps.

- From Admin UI main menu open "System Admin" node.
- Go to Security -> Access Control
- By default three default ACLs are listed:

HTTP - rules for the Web server

NEWS - rules for the Internet News

PROXY - rules for the Web Proxy Server

PSH and PSH-SSL - available only when the pubsubhub_dav.vad is installed.

Figure 14.13. Access Control

- New ACLs can be added by entering a list name and clicking "Add" button.
- Existing ACLs can be edited by clicking on the link "Edit" beside each listed ACL.
- To add new rules, enter the requested information and press button "Add".
- To change the order of the rules use the "top", "bottom", "up" and "down" links.
- ACL's can be removed using the Delete button.

Alternately the HTTP_ACL table can be directly manipulated with SQL. To add new rule:

```
INSERT INTO HTTP_ACL (HA_LIST, HA_ORDER, HA_CLIENT_IP, HA_RATE, HA_FLAG) values
('list_name', <order number>, '*pattern*', <hits_per_second_number>, [1/0]);
```

To remove existing rule:

```
DELETE from HTTP_ACL where HA_LIST = 'list_name' and HA_ORDER = <order number>
and HA_FLAG = [1/0] and HA_CLIENT_IP = '*pattern*';
```

14.2.3. Using ACL's Within Application Logic

The `http_acl_get()` function can be used to test an address against an ACL. The `http_client_ip()` function can be used to determine the IP address or DNS name of a client machine.

Example 14.4. Using ACL's with Application Logic

To restrict a 'foo.bar' (network 333.333.333.0) from accessing a SOAP service one could use the following:

```
-- deny access from '333.333.333.*'
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip) values ('MY_SOAP', 1, 1, '333.333.333.*')
-- allow
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip) values ('MY_SOAP', 2, 0, '*');

-- a procedure exposed as SOAP service

create procedure SumService (in a int, in b int) returns int
{
  if (0 <> http_acl_get ('MY_SOAP', http_client_ip ()))
    signal ('42000', 'Access denied');
  return (a + b);
}
```

14.2.4. Predefined ACLs

The following ACLs are predefined and have special treatment in Web Server processing:

HTTP. General Web server ACL, applying rules to it controls access to the Web server. Thus if this ACL is managed via web UI one must pay attention not to disable the current connection and render the administration UI inaccessible. The ACL rules for 'HTTP' must contain HA_ORDER, HA_CLIENT_IP (pattern) and HA_FLAG (access flag) only. The rest of column values are ignored. To add or remove rules to that list see 'ACL definition/removal' where HA_LIST must be equal to 'HTTP'. The value of client's IP address will be tested against rules.

NEWS. controls access to the separate Internet News groups, restricting POST or READ access to them.

All valid rules for 'HTTP' are also valid for 'NEWS' with following difference:

HA_OBJECT must be specified as ID of News group to control

HA_RW must be specified as 0/1 to designate which action on group to control: read or post.

The HA_LIST must be equal to 'NEWS' if control is managed with SQL statements. The HA_LIST must be equal to 'NEWS'.

PROXY. This controls access to the Web Proxy Server. Note that Proxy service is disabled by default and can be enabled with 'HTTPProxyEnabled' INI setting. This ACL is similar to the HTTP ACL. Additionally, the pattern in HA_DEST_PATTERN must match the destination server. In this way certain destinations can be restricted.

Note:
HTTP ACLs affect PROXY rules. Therefore if HTTP list rejects a request from a particular client, the proxy access from there also will be rejected.

Example 14.5. Adding/removing ACL's

To allow access from localhost only:

```
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip) values ('HTTP', 1, 0, '127.0.0.1');
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip) values ('HTTP', 2, 1, '*');
```

To allow only local addresses (private.net/192.168.0.0) to access proxy server.

```
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip, ha_dest_ip)
             values ('PROXY', 1, 0, '192.168.1.*', '*');
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip, ha_dest_ip)
             values ('PROXY', 2, 1, '*', '*');
```

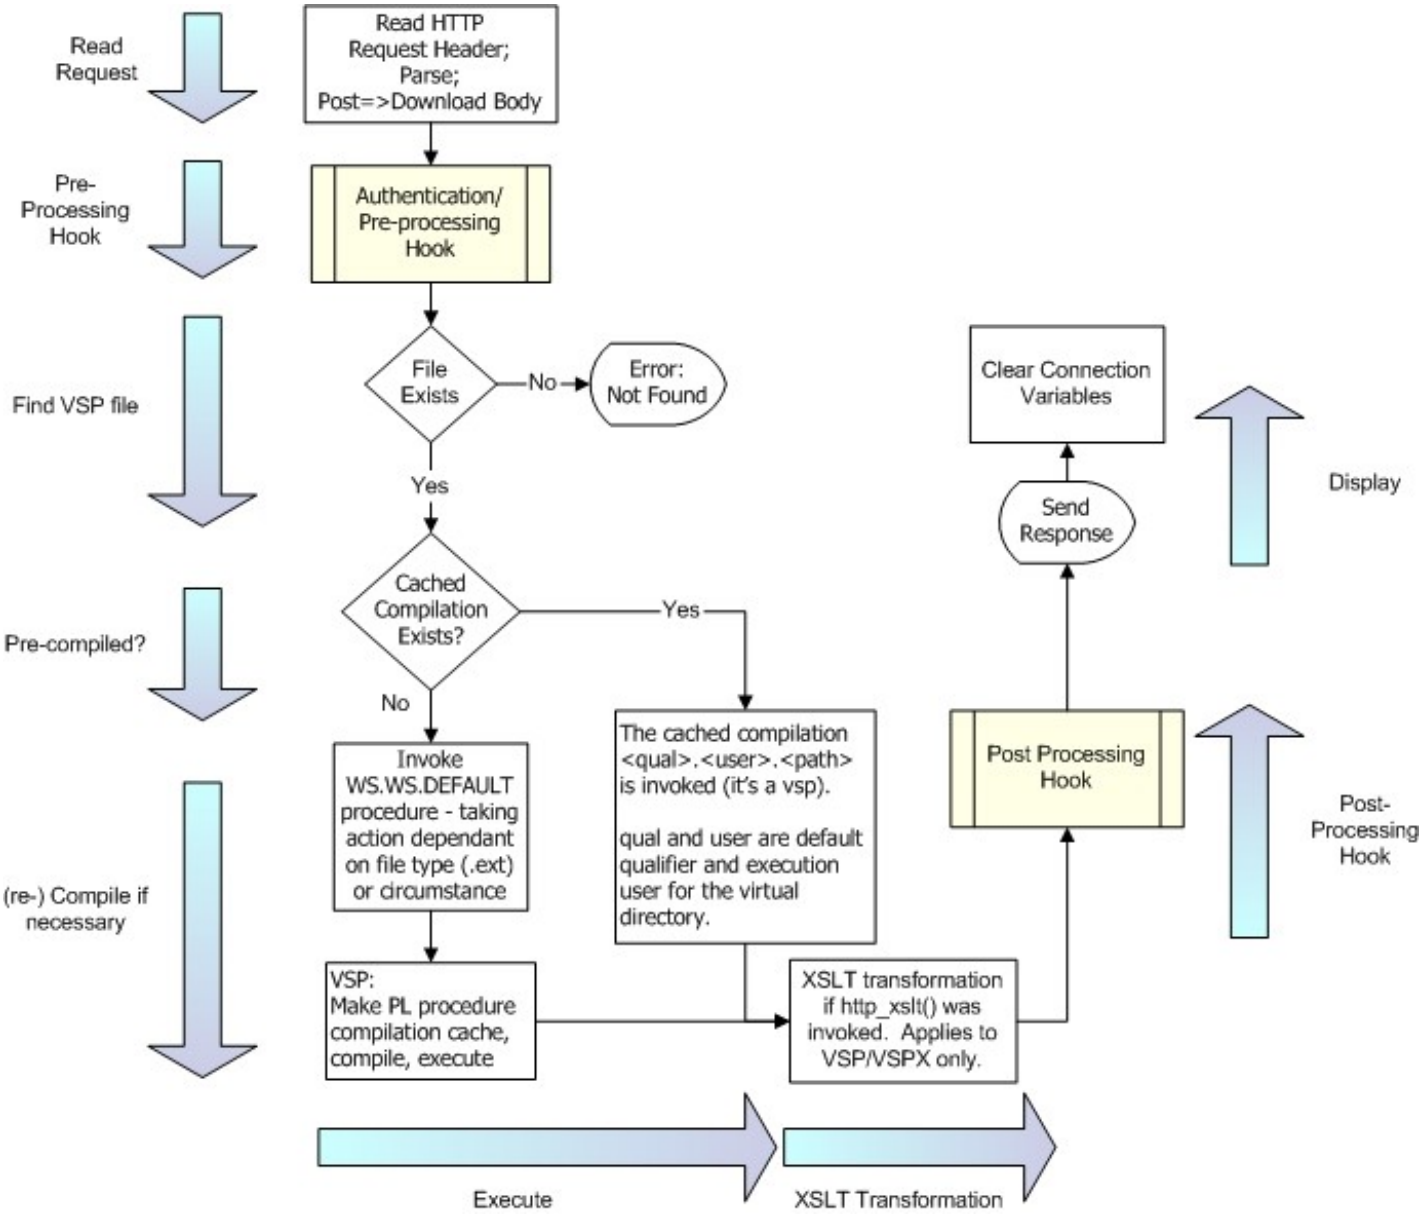
To deny web access from some domain (bad.domain/333.333.333.0)

```
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip) values ('HTTP', 1, 0, '*');
insert into http_acl (ha_list, ha_order, ha_flag, ha_client_ip) values ('HTTP', 2, 1, '333.333.333.*');
```

14.3. Virtuoso Server Pages (VSP)

The Virtuoso Server Pages subsystem is an integral part of the Virtuoso server. A VSP page is a file system or DAV resident resource that contains Virtuoso/PL code intermixed with HTML or other static content.

Figure 14.14. VSP Conceptual Diagram



Virtuoso can serve Web pages to HTTP 1.0 and HTTP 1.1 clients. The HTTP document root is set by the ServerRoot parameter in the [HTTPServer] section of the Virtuoso INI file. By default this is set to `vsp` sub-directory of the installation. If this parameter is not set, then the default document root will be the server's working directory.

Executing VSP Pages. Directories under the ServerRoot directory, including the root itself are not automatically allowed to execute dynamic pages such as VSP. A virtual directory must first be created with an appropriate VSP user assigned to permit execution of dynamic pages. After this, Virtuoso will execute files with a "`.vsp` " extension as a VSP page.]

The VSP Stored Procedure. Each VSP page constitutes a Virtuoso stored procedure named after the URI of the page by taking the URI and pre-pending the WS.WS. qualifier and owner. Hence the page `/test.vsp` becomes the procedure `"WS"."WS"."/test.vsp"` . This is automatically performed when a page is first requested. Subsequent requests to the page will not reference the file. The VSP engine will check for changes in the `.vsp` source file before calling the procedure and re-compile as required. The ws_proc_def() SQL function can be used to explicitly update the procedure if the .vsp file is changed.

The VSP Transaction. Each URL is executed in its own transaction. All SQL statements in a page procedure, whether on local or remote data, make up one transaction, unless transaction control statements are explicitly used to divide the page into multiple transactions. If the page procedure returns through completing execution or through a return statement or as a result of a 'no data found' condition, the transaction is implicitly committed. If this commit fails, the output is discarded and the error message indicating the commit failure is sent to the HTTP client. If a VSP procedure returns as a result of an error the transaction is rolled back and the output discarded. The client gets the SQL error message as the HTML body of the reply. A VSP procedure can commit or roll back explicitly with the `commit work` or `rollback work` PL statements.

If the client closes the connection to the server while server-side processing is taking place this will be detected by the server and the transaction will be eventually interrupted and rolled back in the same way as if an ODBC client had disconnected. To control the server reacting or not on the HTTP client disconnecting the SET HTTP_IGNORE_DISCONNECT = ON/OFF should be used.

Each VSP page-procedure is called with three arguments:

path - the URI path of the VSP page itself.

params - the parameters from a previous POST to the server.

lines - the complete set of headers received from the calling client.

Each VSP procedure runs in a context that implicitly contains the stream to the HTTP client. The arguments of the VSP page procedure are represented as arrays of strings. For example, GETing the URL:

```
http://www.test.net/x/y.vsp?arg1=1&arg2=2
```

would cause the following arguments to be given to the page-procedure `WS.WS./x/y.vsp` :

```
path     ('x', 'y.vsp')
params   ('arg1', '1', 'arg2', '2')
lines    ('GET /x/y.vsp?arg1=1&arg2=2 HTTP/1.1', 'Host: www.test.net', ...)
```

Arrays are marked in parentheses with elements separated by commas. The page procedure is called as a result of either a GET or POST request in either HTTP/1.0 or HTTP/1.1. In the event of a POST request the params contains the post data.

Virtuoso can be configured to proxy certain requests to another web server. This allows using another web server for running cgi-bin's, Java servelets or other web server functions. Virtuoso, however, is capable of hosting many other dynamic engines also, such as PHP, JSP and ASP.Net.

14.3.1. VSP Markup & Basic Functions

All VSP specific markup is represented as a processing instruction (<? ... ?>).

```
<?vsp
  statement ;
  statement ;
  ...
 ?>
```

This markup introduces Virtuoso PL code to a VSP page, which otherwise may normally contain HTML markup. The code enclosed must begin and end at a statement boundary but a compound statement may begin in one <?vsp tag and end in another. Code outside of these blocks is ignored by Virtuoso and placed directly on the HTTP stream to be sent to the client.

See Also:

The SQL Procedure Language Guide chapter.

Several functions exist to allow VSP code to send data to the HTTP stream. They are basically the same but offer different escaping mechanisms to suit different purposes:

```
http (in value varchar, in stream any);

http_value ( in value any, in tag varchar, in tag varchar, in stream any);

http_url ( in value any, in tag varchar, in stream any);
```

These functions output their *value* argument to the specified stream with varying escaping. The value argument may be any scalar object, i.e. string, date or number and will automatically be cast to varchar before further processing.

`http()` will print out the contents of *value* cast to string without any modification.

`http_value()` will use HTML escapes such that '< ' will be output as '`<` '.

The `http_url()` function will use URL escapes such that '+' replaces spaces and hex escapes like %25 will replace '%'. If `http_value()` gets an XML entity returned by a path expression it outputs the serialization of the entity, including children. This is not the string value since this has the entity start and end tags and other markup. The tag argument allows specifying a tag in which the value is to be enclosed. A non-string value, e.g. 0 or null will cause no tag to be put around the value.

The stream argument may be omitted, in which case it defaults to the HTTP client of the calling procedure. If present, a value of integer 0 will mean the http client. If non-0 the value must be an object returned by string_output() .

These HTTP functions are commonly combined with `sprintf()` which allows string composition based on a template. When using sprintf() to compose data to send to the user agent the %V and %U letters can be used to introduce escapes similar to http_value and http_url, respectively.

Example 14.6. HTTP Functions

```
http (' % <b>')           ' % <b>'
http_value (' % <b>')     ' % &lt;b&gt;'
http_url (' % <b>')       '+%25+<b>'
http_value (12, 'li')     '<li>12</li>'
```

Markup Short-hands

VSP markup short-hands exist for the `http_value()` and `http_url()` functions to perform the same task outside of a VSP code block. This can improve readability of VSP pages.

```
<?= expression ?>  equiv.  http_value()

<?/ expression ?>  equiv.  http_url()
```

These markups are shorthand for substituting values of expressions into the output. The `<?=` tag accepts a SQL expression and casts the value into a string, which is sent to the output. The `<?/` markup sends the value of the expression to the client with HTTP URL escapes.

Example 14.7. VSP Markup

Here is a very simple example of making a two column HTML table from the results of a "select" SQL statement. First using normal functions:

```
<html>
<h2>List of Users</h2>
<table>
<?vsp
  for (select u_name, u_password from sys_users ) do {
    http('<tr><td>');
    http (u_name);
    http('</td><td>');
    http (u_password);
    http('</td></tr>');
  }
?>
      </table>
</html>
```

This fragment outputs a table of user names and passwords. We have chosen to not end the code block until the end of the result so we have repeatedly used the `http()` function to output parts of the table also.

Now the same code but including shorthands:

```
<html>
<h2>List of Users</h2>
<table>
<?vsp for (select u_name, u_password from sys_users ) do { ?>
  <tr>
    <td><?=u_name ?></td>
    <td><?=u_password ?></td></tr>
      <?vsp } ?>
      </table>
</html>
```

14.3.2. Access Request Information

Request information, resulting from an HTTP POST, is available via the *params* vector. The params vector is always available for the purpose in a VSP context. Similarly the *lines* and *path* vectors are available for the HTTP headers and URL path respectively.

Parameters stored in the params vector are stored in keyword-value pairs, such that keywords are stored in the even elements, values in the odd numbered elements. Vectors and arrays can be accessed using the `aref()` and `aset()` functions, however, the exact position of parameters is seldom known. The `get_keyword()` function can be used to return the value of a given parameter. You can specify a default value to return in case the parameter you are looking for is not found.

```
get_keyword ('param_name' , vector [, opt_default_value' ]);
```

If a default value other than '' (empty-string) is not required then a short-hand can be used instead.

```
{?'param_name'}
```

is equivalent to `get_keyword ('param_name' , 'params' );`

Since `get_keyword()` returns only strings, you will find that `cast` ing or conversion functions such as `atoi()` are very useful here.

Example 14.8. Reading the params Vector

Consider retrieving the following page by means of the URL:

```
http://myvirtuoso/test.vsp?arg1=1&arg2=test

<html>
 <body>
  <h1>Test Params</h1>
  <?vsp
  declare _arg1 integer; --   the underscore helps to differentiate from
  declare _arg2 varchar; --   the keyword name, whereas the variable names
  declare _arg3 varchar; --   help use remember which is which.

  _arg1 := atoi(get_keyword('arg1', params));
  _arg2 := {?'arg2'};
  _arg3 := get_keyword('arg3', params, 'was empty'};

  ?>
  <p>values returned:</p>
  <p>arg1: <?=_arg1?></p>
  <p>arg2: <?=_arg2?></p>
  <p>arg3: <?=_arg3?></p>
 </body>
</html>
```

See Also:

See Also:

`get_keyword()`

`atoi()`

`aref()`

`aset()`

cast

Note:
Sometimes a POST can supply a large amount of data, such as from an <INPUT type="file">. When the length of the parameter data exceeds 5,000,000 octets the result is stored as a string session in the params array. In these cases the value should not be copied or converted to a string, it is likely to be truncated. The value should be stored as a BLOB or an external file. When processing possibly large input fields in a form either the fourth parameter to `get_keyword()`/`get_keyword_ucase()` should be set to 1 or they should be accessed through `aref_set_0()`.

14.3.3. Errors in Page Procedures

VSP pages can declare handlers for errors using the normal handler declaration or whenever ... goto construct. Any unhandled error causes the procedure to be terminated and the error message to be sent to the HTTP client instead of the output. Because terminating the page output at an arbitrary point would probably result in not well formed output all the output up to the point of the error is discarded.

If the SQL state signalled with the error is VSPRT the output generated up to the point where the error was signalled is sent as such to the user agent. This special SQL state is useful together with the http_rewrite function for things like sending a redirect based on a condition detected in the middle of page processing. The http_rewrite function will clear all output buffered so far and signaling VSPRT will make sure that whatever output is generated after http_rewrite goes unmodified to the user agent.

14.3.4. /INLINEFILE HTTP Server Pseudo-Directory

This pseudo directory provides a way for a VSP page to have full control over the data sent to the client user-agent, for example to send files to it and to handle the HTTP response attributes.

URIs starting with /INLINEFILE are handled through a VSP procedure instead of being searched for in the HTTP root directory. This special URI has the following syntax:

```
/INLINEFILE/some_file_name?VSP=some_vsp&arg1=x&arg2=y.....
```

Upon receipt of such a URI, Virtuoso will execute the "some_vsp" VSP page with the parameters following the VSP parameter. The VSP page can adjust the HTTP response header attributes using the `http_header()` function to reflect the content of the HTTP body, such as specifying the encoding through "Content-Encoding" attribute, or a MIME type through "Content-Type" attribute).

Example 14.9. Using /INLINEFILE

Here is a simple example for showing JPEG images stored in DAV. The page will list the first ten images found in the DAV resources table as hyper-links. Clicking on them will fetch the content and display using /INLINEFILE.

```
<?vsp
  if ({?'getfile'} <> '')
    {
      http_header ('Content-type: image/jpg\t\n');         -- set the header to jpg
      declare image any;
      select RES_CONTENT into image from WS..SYS_DAV_RES
        where RES_ID = atoi({?'id'});                      -- download image from WebDAV
      http(image);                                         -- table and display
      return;
    }
  ?>
<html>
 <body>
 <h1>Using /INLINEFILE to display images from the database</h1>
```

```
 <table>
  <tr>
   <td>

<?vsp for (select top 10 RES_ID, RES_NAME from WS..SYS_DAV_RES where right(RES_NAME, 3) = 'jpg') do {?>
 <a href="?id=<?=RES_ID?>"><?=RES_NAME?></a><br>
<?vsp } ?>

   </td>
   <td>
    <p><img src="/INLINEFILE/picture.jpg?VSP=<?/http_path()?>&getfile=yes&id=<?={?'id'}?>"></p>
    <p><a href="/INLINEFILE/picture.jpg?VSP=<?/http_path()?>&getfile=yes&id=<?/{?'id'}?>">download</a></p
   </td>
  </tr>
 </table>
 </body>
</html>
```

Note:

Note the use of the `http_path()` function to find the full path of the originating VSP file.

Also note the call to `http_header()` to set the appropriate content type for the returned data. When Virtuoso retrieves files normally, it will consult the system table `WS.WS.SYS_DAV_RES_TYPES` for types based on the file extension. We do not need to refer to the table in our example because we are making sure that only JPEGs are being returned.

`http_header()`

`http_path()`

14.3.5. Beyond Basics

All output from VSP page procedures is buffered into a local string stream before being sent out. This is done so as to support the HTTP/1.1 required content length and to allow recovery from errors.

```
http_rewrite ( in stream any);
```

This clears any previous output to the stream. If the stream is omitted or 0 the stream is the HTTP client stream of the calling procedure.

```
http_file ( in path varchar);
```

This function sends a file to the HTTP client as a response to the current request. Any other output that may have been generated by the calling procedure will be discarded and the contents of the file will be the exclusive response to the current HTTP request together with appropriate headers. The file will only be sent after the procedure handling the current HTTP request has returned. The file name is thus not validated until the calling procedure has returned.

```
http_get( in uri varchar, out headers varchar);
```

This function retrieves the document specified by the URI by HTTP and returns the data of the response. The header output parameter is set to be an array with an element for each line of the response's HTTP header. Each line is a varchar object in the containing array. The header parameter is optional.

The URI is of the form `host[:port]<path>` , e.g '`www.openlinksw.com:80/index.html` '. The port, if omitted, defaults to 80. The data following the headers is not processed in any way. No content transfer encodings are decoded but an eventual content transfer encoding header can be found in the header array.

```
http_flush();
```

This function generates a response header, flushes a stream and disconnects the client, however, the server will continue with the execution of the PL code in VSP page. The final result will never be sent to the client. This is useful when a page makes a long transaction and we do not wish the client to wait until its end, which may result in a time-out. Suppose we have the retrieval of news from many targets, each a thousand messages. We start from a VSP page process, inside it we put into the internal stream

(using http, http_value etc.) redirect code and call http_flush. The client can read the response and go to a status page that can display number of messages retrieved, which may need refreshing a few times.

```
http_proxy (in host_and_port varchar, in header_lines any, in post_parameters any)
```

The function http_proxy() is used to send request in header_lines and post_parameters to the host_and_port, read the response and send it back to the client. The http_proxy() function can be used inside a VSP page to send a request to an external web server and automatically route the reply sent by this remote server to the client of the VSP page calling http_proxy(). The output which can generated (with http functions, etc.) before and after http_proxy is called will be discarded before sending the result of link retrieval to the user-agent.

Example 14.10. Virtuoso Proxy

```
...
<?vsp
  http ('this never be displayed');
  http_proxy ('www.foo.com', vector ('GET / HTTP/1.0'), NULL);
  http ('and this also');
?>
...
```

Virtuoso HTTP Server Character Set Settings

When the HTTP server returns the HTTP header to the client it appends charset=xxxx to the Content-Type: HTTP header fields. This informs the client user agent, the web browser, as to the character set of the content to be displayed correctly. It uses the Web server charset to correctly format values resulting from the `http_value()` function or the VSP equivalent <?= ...>. Wide values and XML entities, resulting from any XML processing functions like xpath_contains, get represented using the "HTML/XML transformation".

The default web server charset is governed by the *Charset* setting defined in the Virtuoso INI file . If no default charset is specified then Virtuoso will use ISO-8859-1.

The HTTP character set can be changed during an HTTP session using: *set http_charset='charset_name';* .

The XSLT output encoding can also be specified to over ride the server default setting.

Session Management and State Variables

The Virtuoso HTTP session management consists of functions for session variables manipulation and hooks for saving and restoring session variables.

Session management must be enable by setting the flag for persistent session variables in the virtual directory mapping. Virtual directory mappings use the *persistent_session_variables* flag, which when specified, session variables can be used in a post-process function to determine if the session variables content must be stored on to the session table or not.

The post-processing function hook can be any user-defined Virtuoso/PL procedure, it will be executed every time after processing of the active page.

14.3.6. Long HTTP Transactions

Long running tasks may be invoked by web clients. In such a case, the server should return a page for the user agent much before the tasks's completion in order to provide feedback and avoid timeouts. Also the long running task should not be interrupted by the user agent disconnecting. The `http_flush()` function will send the reply accumulated thus far to the user agent and then disconnect it. In effect, this is a generic mechanism for starting an asynchronous thread.

Starting long running tasks may lead to denial of service. To prevent this we can use status and stop functions to check processes and kill them if necessary.

We can retrieve the URL, client IP-address, and process status code for all currently running VSP requests, then use this information to isolate and eliminate a process.

`http_pending_req()` Lists the processes.

http_kill() can be used to kill them.

14.3.7. Using chunked encoding in HTTP 1.1

It is sometimes desirable to use the HTTP 1.1 chunked encoding to send data to HTTP clients. Examples of such include status pages or streaming applications. Note that the possibility of using chunked encoding depends on external factors such as whether the client browser supports chunked encoding. So a server page can request turning on the chunked encoding, but should handle the case should it not be available.

Note that in order to successfully turn on the chunked encoding the page should not be using the `http_xslt()` . Also all reply headers set by the `http_header()` are silently ignored after the mode is set.

The `http_flush()` (with 1 as a value for it"s optional argument) is used to request turning on the chunked encoding. If the client"s user agent supports the encoding, then the data accumulated so far in the server"s output buffer are sent to the client as the first chunk, the request is put in special "chunked mode" and the `http_flush()` returns a non-zero integer. When in that mode a new chunk is sent to the client either when the internal 4k buffer is filled up or when the client calls `http_flush()` again to flush the buffer and send it as a chunk. The client disconnection is handled as usual .

14.3.8. Making Simple Dynamic Web Pages

The directory where the pages reside must be marked as executable. Use the vhost_define function or the Administration Interface to do this:

```
vhost_define (lpath=>'/example_location', ppath=>'/example_location/', vsp_user=>'demo');
```

The usual way to make an Dynamic page is to make a HTML skeleton and insert Virtuoso/PL code in appropriate places to fill in the rest dynamically. Consider the following example as a demonstration of such technique. Note that the example is made in four steps but in practice this can be one.

Suppose we have a table Demo.demo.Shippers (from the Demo database of the standard distribution). We can make a simple page for editing it.

1. **Building The HTML Skeleton.** We define one form for editing and adding entries and a table for listing the existing shippers.

```
<HTML>
  <BODY>

    <!-- edit form -->

    <FORM name="ShippersForm" method="POST" action="shippers.vsp">
       <INPUT type="hidden" name="ShipperID" value="">
       <TABLE>
         <TR>
           <TD>Company Name</TD>
           <TD><input type="text" name="CompanyName" value=""><!-- CompanyName -->

</TD>
```

```
          </TR>
          <TR>
            <TD>Phone</TD>
            <TD><INPUT type="text" name="Phone" value=""><!-- Phone number -->

</TD>
          </TR>
          <TR><TD colspan="2"><input type="submit" name="accept" value="Accept"></TD></TR>
        </TABLE>
    </FORM>
    <!-- end of form -->

    <!-- list of entries -->

    <TABLE>
       <TR><TD>Company Name</TD><TD>Phone #</TD><TD colspan="2">Action</TD></TR>
       <!--TR><TD>CompanyName</TD><TD>Phone</TD><TD>Edit URI</TD><TD>Delete URI</TD></TR-->

    </TABLE>
    <!-- end of list -->

  </BODY>
</HTML>
```

2. **Filling a List of Entries.** We have added in part 'list of entries' one active part (for select ...). And using <?=...?> shortcut we have made for each row in database table one row in table defined in step 1. Also we have added two useful links 'Edit' and 'Delete' with URL parameter 'EDIT' and 'DELETE' whose value is equal to the primary key value of the row;

```
<HTML>
  <BODY>

    <!-- edit form -->

    <FORM name="ShippersForm" method="POST" action="shippers.vsp">
       <INPUT type="hidden" name="ShipperID" value="">
       <TABLE>
         <TR>
           <TD>Company Name</TD>
           <TD><input type="text" name="CompanyName" value=""><!-- CompanyName -->

</TD>
         </TR>
         <TR>
           <TD>Phone</TD>
           <TD><INPUT type="text" name="Phone" value=""><!-- Phone number -->

</TD>
         </TR>
         <TR><TD colspan="2"><input type="submit" name="accept" value="Accept"></TD></TR>
       </TABLE>
    </FORM>
    <!-- end of form -->

    <!-- list of entries -->

    <TABLE>
       <TR><TD>Company Name</TD><TD>Phone #</TD><TD colspan="2">Action</TD></TR>
       <!--TR><TD>CompanyName</TD><TD>Phone</TD><TD>Edit URI</TD><TD>Delete URI</TD></TR-->

       <?vsp
         for select ShipperID, CompanyName, Phone from Demo.demo.Shippers do
          {
       ?>
       <TR>
         <TD><?=CompanyName?></TD>
         <TD><?=Phone?></TD>
         <TD><a href="shippers.vsp?EDIT=<?=ShipperID?>">Edit</a></TD>
         <TD><a href="shippers.vsp?DELETE=<?=ShipperID?>">Delete</a></TD>
       </TR>
       <?vsp
          }
```

```
      ?>
    </TABLE>
    <!-- end of list -->

  </BODY>
</HTML>
```

3. **Retrieving Parameters and Filling in The Form.** We must retrieve the parameters 'Delete' and 'Edit' from the URL and fill in the form elements

```
<?vsp
declare company_name, phone_number varchar;
declare shipper_id, operation integer;
declare shipper_info
  cursor for select CompanyName, Phone
    from Demo.demo.Shippers where ShipperID = shipper_id;

company_name := '';
phone_number := '';
operation := 0;

shipper_id := atoi (get_keyword ('EDIT', params, '0'));

if (shipper_id > 0)
  {
    whenever not found goto not_found_any;
    open shipper_info (prefetch 1);
    fetch shipper_info into company_name, phone_number;
not_found_any:
    close shipper_info;
    goto display_page;
  }

shipper_id := atoi (get_keyword ('DELETE', params, '0'));

if (shipper_id > 0)
  {
    delete from Demo.demo.Shippers where ShipperID = shipper_id;
    goto display_page;
  }

display_page:

?>

<HTML>
  <BODY>

    <!-- edit form -->

    <FORM name="ShippersForm" method="POST" action="shippers.vsp">
       <INPUT type="hidden" name="ShipperID" value="<?=shipper_id?>">
       <TABLE>
         <TR>
           <TD>Company Name</TD>
           <TD><input type="text" name="CompanyName" value="<?=company_name?>"</TD>
         </TR>
         <TR>
           <TD>Phone</TD>
           <TD><INPUT type="text" name="Phone" value="<?=phone_number?>"</TD>
         </TR>
         <TR><TD colspan="2"><input type="submit" name="accept" value="Accept"></TD></TR>
       </TABLE>
    </FORM>
    <!-- end of form -->

    <!-- list of entries -->

    <TABLE>
       <TR><TD>Company Name</TD><TD>Phone #</TD><TD colspan="2">Action</TD></TR>
       <!--TR><TD>CompanyName</TD><TD>Phone</TD><TD>Edit URI</TD><TD>Delete URI</TD></TR-->

       <?vsp
```

```
          for select ShipperID, CompanyName, Phone from Demo.demo.Shippers do
           {
        ?>
        <TR>
          <TD><?=CompanyName?></TD>
          <TD><?=Phone?></TD>
          <TD><a href="shippers.vsp?EDIT=<?=ShipperID?>">Edit</a></TD>
          <TD><a href="shippers.vsp?DELETE=<?=ShipperID?>">Delete</a></TD>
        </TR>
        <?vsp
           }
        ?>
    </TABLE>
    <!-- end of list -->

  </BODY>
</HTML>
```

We have added a section to the top of the page that we use to recognize what operation to perform and do the appropriate action in the database. In the case of editing we use the values input on the form.

4. **Editing Form Logic.** We have a logic in the same initialization part of the page that retrieves a 'ShipperID' parameter, so if this parameter exists in the params array then the operation is to perform an insert, otherwise we must update a record.

```
<?vsp
declare company_name, phone_number varchar;
declare shipper_id integer;
declare shipper_info
  cursor for select CompanyName, Phone
    from Demo.demo.Shippers where ShipperID = shipper_id;

company_name := '';
phone_number := '';

shipper_id := atoi (get_keyword ('EDIT', params, '0'));
-- If the current operation is edit then we retrieve the Company Name and Phone
if (shipper_id > 0)
  {
    whenever not found goto not_found_any;
    open shipper_info (prefetch 1);
    fetch shipper_info into company_name, phone_number;
not_found_any:
    close shipper_info;
    goto display_page;
  }

shipper_id := atoi (get_keyword ('DELETE', params, '0'));

-- If the operation is delete then delete it (if any error
-- occurred then HTTP server will handle it)
if (shipper_id > 0)
  {
    delete from Demo.demo.Shippers where ShipperID = shipper_id;
    shipper_id := 0; -- reset it to prevent submission of wrong shipper id
    goto display_page;
  }

-- If pressed button Accept then we can recognize the operation
if ('' <> get_keyword ('accept', params, ''))
  {
    shipper_id := atoi (get_keyword ('ShipperID', params, '0'));
    company_name := get_keyword ('CompanyName', params, 'unknown');
    phone_number := get_keyword ('Phone', params, 'N/A');
    -- the old entry going edited
    if (shipper_id > 0)
        update Demo.demo.Shippers set CompanyName = company_name, Phone = phone_number
            where ShipperID = shipper_id;
    else -- this is an new entry
      {
        shipper_id := coalesce ((select max(ShipperID) from Demo.demo.Shippers), 0) + 1;
        insert into Demo.demo.Shippers (ShipperID,CompanyName,Phone)
```

```
            values (shipper_id,company_name,phone_number);
        }
      company_name := ''; -- we clear all entered data
      phone_number := '';
      shipper_id := 0; -- to prevent setting of wrong shipper id in form
    }

display_page:

?>

<HTML>
  <BODY>
    <H3>Editing a shipment companies</H3>
    <!-- edit form -->

    <FORM name="ShippersForm" method="POST" action="shippers.vsp">
       <INPUT type="hidden" name="ShipperID" value="<?=shipper_id?>">
       <TABLE>
         <TR>
           <TD>Company Name</TD>
           <TD><input type="text" name="CompanyName" value="<?=company_name?>"</TD>
         </TR>
         <TR>
           <TD>Phone</TD>
           <TD><INPUT type="text" name="Phone" value="<?=phone_number?>"</TD>
         </TR>
         <TR><TD colspan="2"><input type="submit" name="accept" value="Accept"></TD></TR>
       </TABLE>
    </FORM>
    <!-- end of form -->

    <!-- list of entries -->

    <TABLE>
       <TR><TD>Company Name</TD><TD>Phone #</TD><TD colspan="2">Action</TD></TR>
       <!--TR><TD>CompanyName</TD><TD>Phone</TD><TD>Edit URI</TD><TD>Delete URI</TD></TR-->

       <?vsp
         for select ShipperID, CompanyName, Phone from Demo.demo.Shippers do
          {
       ?>
       <TR>
         <TD><?=CompanyName?></TD>
         <TD><?=Phone?></TD>
         <TD><a href="shippers.vsp?EDIT=<?=ShipperID?>">Edit</a></TD>
         <TD><a href="shippers.vsp?DELETE=<?=ShipperID?>">Delete</a></TD>
       </TR>
       <?vsp
          }
       ?>
    </TABLE>
    <!-- end of list -->

  </BODY>
</HTML>
```

5. **Final Remarks.** The page for shippers does not have any specific error-handling. If there are any SQL errors produced the HTTP server will display the error number and the server error message. For example, if we trying to delete an record of a predefined shippers we would have a foreign key violation to which the server would respond:

```
'SQL Error S1000 DELETE statement conflicted with
  COLUMN REFERENCE constraint "Orders_Shippers_ShipVia_ShipperID"'
```

We can, however, add PL code to handle errors and display a different page.

14.3.9. Generation of non-HTML output

VSP pages are not restricted to generating only HTML markup. In order to generate non-HTML markup the VSP page MUST conform to the target format specification, for example if XML output is needed, the markup MUST follow XML syntax rules.

The output sent to the user agent is entirely controlled by the scripting on the page, no constant headers beyond the required HTTP ones are added by the serber.

Also it is important when output is not HTML that the HTTP header field 'Content-Type' be set to appropriate MIME type (for example 'text/xml', 'text/plain' etc) using `http_header()` .

Example 14.11. XML generation

The following example shows how an XML document can be generated using a VSP page

```
<?vsp
    -- source of the xmldemo.vsp
    declare txt varchar;
    http_header ('Content-Type: text/xml\r\n');
    txt := 'this is a XML test';
?><?xml version="1.0" ?>
<document>
    <para><?= txt ?></para>
</document>
```

Example 14.12. WML generation

The following example shows how a WML page can be generated using a VSP page

```
<?vsp
    -- source of the wmldemo.vsp
    declare txt varchar;
    http_header ('Content-type: text/vnd.wap.wml\r\n');
    txt := 'this is a WML test';
?><?xml version="1.0" ?>
<!DOCTYPE wml PUBLIC "-//WAPFORUM//DTD WML 1.1//EN" "http://www.wapforum.org/DTD/wml_1.1.xml"
<wml>
    <card>
        <p><?= txt ?></p>
    </card>
</wml>
```

WML Tutorials

14.3.10. Post VSP XSLT Transformation Mode

The Virtuoso server can perform server-side XSLT transformations on the internal stream data. Suppose we have an XML document, we can tell the HTTP server to invoke XSLT processor before sending the reply to the user agent. We do this by making a call to the http_xslt() function inside VSP or any procedure called from it and pass the URL of the stylesheet and probably some parameters.

`http_xslt(in` *`style_sheet_URI`* `varchar [, in` *`parameters`* `any])`

The VSP page will produce an XML document, rather than HTML. The XSL stylesheet will then produce the required output for the user-agent, which could be more XML or HTML.

The XSL stylesheet could also be generated using VSP.

Example 14.13. In Server Transformation of XML

```
<?vsp
declare ses any;
ses := string_output ();
xml_auto ('select ShipperID, CompanyName, Phone from Demo.demo.Shippers
```

```
  for xml auto element', '', ses);

http ('<list>');
http (string_output_string (ses));
http ('</list>');
http_xslt ('file:/samples/xslt/shippers.xsl');
?>
```

Where shippers.xsl will have the following content:

```
<?xml version="1.0"?>

<xsl:stylesheet
    version="1.0"
    xmlns:xsl="http://www.w3.org/1999/XSL/Transform">

  <xsl:output method="html"/>

  <xsl:template match="/">
<html>
<head>
<title>Shippers list</title>
</head>
<body link="#0000b4" vlink="#0000b4" bgcolor="#ffffff">
<xsl:apply-templates/>
</body>
</html>
</xsl:template>

  <xsl:template match="list">
<table>
<tr><td>ID</td><td>Name</td><td>Phone</td></tr>
<xsl:apply-templates/>
</table>
</xsl:template>

  <xsl:template match="Shippers">
<tr>
<td><xsl:value-of select="ShipperID"/></td>
<td><xsl:value-of select="CompanyName"/></td>
<td><xsl:value-of select="Phone"/></td>
</tr>
</xsl:template>
</xsl:stylesheet>
```

14.3.11. XML & XSLT Generated VSP Pages

The Virtuoso HTTP server provides a special case for producing VSP pages. For this purpose the extensions .vxml and .vxsl are reserved. If the requested document is named dummy.vxml then the HTTP server will try to locate dummy.vxsl. If the dummy.vxsl exists then it will perform an XSLT transformation using .vxml as a target XML document and .vxsl as a XSLT stylesheet. After successful transformation it will compile a result from it in the usual way and then perform execute.

The requirements are: XML document with extension .vxml, XSLT sheet with the same name, location but extension .vxsl. The location of these files must be set to allow execution (see Virtual Directories Support and Execution Privileges).

Example 14.14. Executable (V)XSL

Source of portfolio.vxml

```
<?xml version="1.0"?>
<?xml-stylesheet type="text/xsl" href="portfolio.xsl"?>
<portfolio xmlns:dt="urn:schemas-microsoft-com:datatypes" xml:space="preserve">
<stock exchange="nyse">
<name>zacx corp</name>
<symbol>ZCXM</symbol>
<price dt:dt="number">28.875</price>
</stock>
<stock exchange="nasdaq">
```

```
<name>zaffymat inc</name>
<symbol>ZFFX</symbol>
<price dt:dt="number">92.250</price>
</stock>
<stock exchange="nasdaq">
<name>zysmergy inc</name>
<symbol>ZYSZ</symbol>
<price dt:dt="number">20.313</price>
</stock>
</portfolio>
```

Source of portfolio.vxsl

```
<?xml version='1.0'?>

<xsl:stylesheet
    xmlns:xsl="http://www.w3.org/TR/WD-xsl">

  <xsl:template match="/">
<HTML>
<BODY>

14.4. Virtuoso Server Pages for XML (VSPX)

VSPX is an XML vocabulary for server generated HTML and XHTML pages that may or may not be bound to native or third-party data sources. VSPX is a framework for building and deploying dynamic web content atop Virtuoso. VSPX offers a widget set and event model which is similar to that of GUI tool kits, providing the developer with much automation for common web development tasks. Many controls are tightly integrated with the Virtuoso database, providing seamless data binding to local or remote relational and XML data. Server side scripting in VSPX is performed in Virtuoso/PL. The VSPX source code consists of HTML or XML with interspersed VSPX specific XML elements which describe the UI control hierarchy of the page.

VSPX covers the following areas:

Rich set of controls, covering all basic HTML plus complex composite controls like data grids and tree browsers.

Session management - Transparent session and session state handling using cookies, URL poisoning or digest authentication.

Form entry validation server and client side.

Single and multi-row controls for viewing and directly updating SQL tables, including scrolling through long result sets.

Repeating and conditional instantiation of UI elements based on run time choices.

Event model for HTTP request handling, providing distinct phases for creating the controls, retrieving data, processing posted data, preserving state and rendering for a user agent.

Object oriented architecture, allowing easy definition of subclasses of existing controls for new functionality. It suffices to implement a new SQL class with a few predefined methods and to implement an XSLT rule for generating the code based on the external XML syntax for the new control.

Easy automatic generation of VSPX pages. The pages being XML, it is simple to automate generating pages based on other data, such as automatically making table maintenance pages based on a SQL table definition.

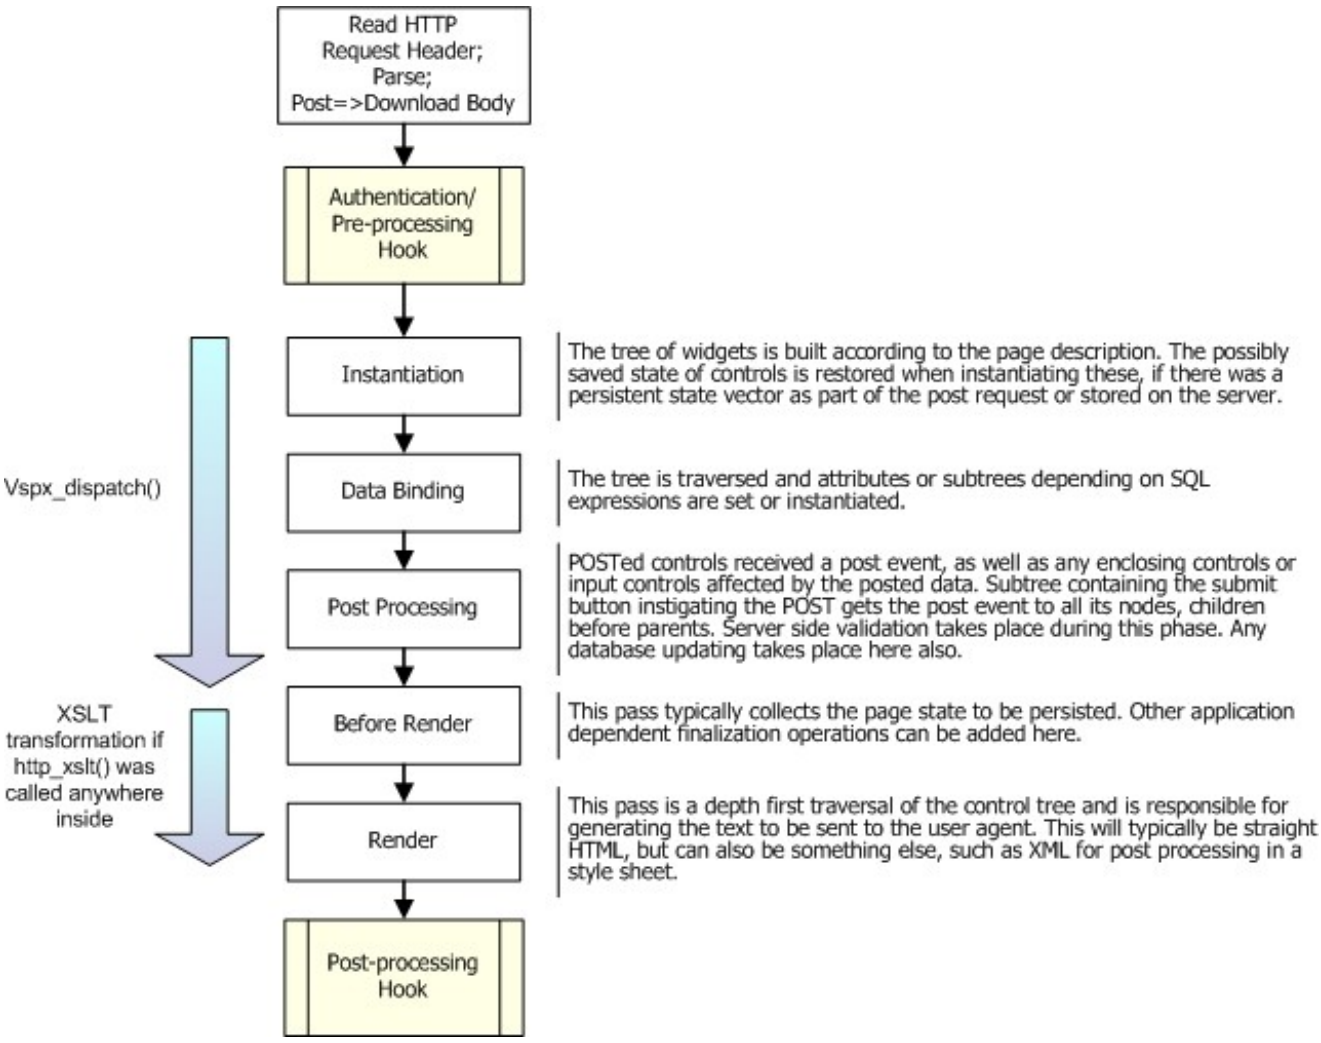
The VSPX development cycle consists of editing .vspx resources in the file system or Virtuoso DAV. The editing can take place using a regular text editor or a supporting HTML editor.

14.4.1. Processing Model

A VSPX page describes a web page in terms of static XHTML plus XML elements in the VSPX namespace, `"http://example.com/vspx/"` . This namespace is abbreviated as `v:` in the rest of this document.

Elements in the `v` namespace introduce VSPX elements, options or controls. Some of these may in turn have HTML children. VSPX elements with HTML children are called templates, as these will process their HTML contents at run time, typically modifying these based on run time data.

Figure 14.15. VSPX Conceptual Diagram



When the page is requested, the system checks whether it is already compiled and compiles it if the compilation is absent or older than the source. The VSPX compilation has two phases: pre-processing and compilation. The first phase expands included files

and applies the external macro XSL-T sheet. The result of which is a single page encapsulating all related components which will be stored in a .vspx-m intermediary file. The result of second phase, compilation is a single .vspx-sql file containing class and method definitions for a subclass of the generic VSPX page class. All code directly derived from the pre-processed page will be found in this file. The file can of course refer to outside Virtuoso/PL code.

The results of compilation process are stored usually in an OS dependent temporary directory. This would be the $TMPDIR for UNIXes or %TMP% for Windows platforms. If these environment variables are not available it will be some default system specific location, such as `/var/tmp` or `/tmp` on Unix's. Note that this temporary storage applies to the VSPX pages that are stored within the file system, for the WebDAV repository the product of compilation is stored as described below. For development purposes the use of temporary storage can be turned off by executing:

```
registry_set ('__no_vspx_temp', '1')
```

from ISQL. In this case both file-system and WebDAV repository will contain .vspx-m and .vspx-sql files in the same place and with the same name as the VSPX source file. VSPX temporary storage can be re-enabled in the same way but using the string value '0' instead of '1'. Note that this is a string rather than a number.

Any VSPX page invocation, whether through the GET or POST HTTP request, consists of the following steps:

- **Instantiation.** The tree of widgets is built according to the page description. The possibly saved state of controls is restored when instantiating these, if there was a persistent state vector as part of the post request or stored on the server.
- **Data Binding.** The tree is traversed and attributes or subtrees depending on SQL expressions are set or instantiated.
- **Post Processing.** If this was a POST request, the control that was mentioned in the POST gets a post event, as well as any enclosing controls or input controls affected by the posted data. The subtree containing the submit button originating the POST gets the post event to all its nodes, children before parents. Post data server side validation takes place during this phase. Any database updating takes place during this processing, typically inside the post handler of the form element, after the post handling of each individual field is complete.
- **Before Render.** The control tree is now assumed to be in a state reflecting the operation intended by the POST or GET. This pass typically collects the page state to be persisted. Other application dependent finalization operations can be added here.
- **Render.** This pass is a depth first traversal of the control tree and is responsible for generating the text to be sent to the user agent. This will typically be straight HTML, but can also be something else, such as XML for post processing in a style sheet.

Just as with VSP pages the code of the page make call http_xslt(), this has the effect of applying the specific stylesheet to the HTML text produced by the render phase. Since output contains HTML tags generated by VSPX controls, the style-sheet should have these as a general rule to leave these unchanged. The http_xslt () is more useful with VSP pages producing XML than with VSPX pages.

14.4.2. Object Model

VSPX controls are SQL user defined type instances, or objects. The SQL object system is substantially similar to any other single inheritance object system, such as that of Java or C#. The XML source code of the VSPX page is processed to generate SQL for instantiating the VSPX control tree. The XML elements and classes may have similar names but are not one to one identical.

All controls, including pages, are instances of a subclass of `vspx_control` . To each VSPX source file corresponds a class named after the file, which inherits the common superclass `vspx_page` . Normally, all code, regardless of which specific control on the page it pertains to, runs inside a method of the page, thus the *self* (like 'this' in Java or C++) refers to the page instance. By convention, the variable *control* references the object representing the control which declares the particular code snippet. The variable `e` represents the event which is at the root of the code being invoked. The event is normally an event object representing a GET or POST HTTP request, but it can also be a user defined event sent to the page by other code on the page or elsewhere.

The page has a data member `vc_children` which contains an array of all top level VSPX controls on the page. Each control in turn has this same variable for referring to subordinate controls, if any.

Each processing pass allows the developer to specify arbitrary SQL code to run in the context of the pass. The code runs in the context of a method of the page object, where the local variable *control* references the control that declares the code in question.

Controls may be enabled or disabled, thus supporting conditional activation and rendering of page parts. Parts may be enabled in function of a page state, for example a search result control is only on after the search text has been posted. Another example is that some controls may only be enabled if a user is logged in.

Code inside a control may locate other controls on the page by name, either starting from the control itself or at the page. Note that when repeating control groups are involved, it is best to start at the leaf and work upwards in the tree, since there can be several identically named children of the page. All controls have a name which is unique in terms of the VSPX source file. Additionally, all controls, including members of repeating groups, have a name which is generated to be unique at run time. The latter is not however constant. The `vc_parent` data member references the parent. `vc_name` is the name as appears in the name attribute of the corresponding XML element. `vc_instance_name` is a page-wide unique name, generated to be different for each possible repetition of the control. The `find_control` method of `vspx_control` can be used to look for a child with a specific `vc_name` .

14.4.3. Keeping Page and Session State

VSPX does not require any particular session management to be in effect to operate. It is in its default form entirely stateless on the server side. There is a mechanism called view state for keeping track of data between consecutive post backs of a single page. This is simply an automatically maintained hidden field which will keep the state of controls which have a state that may be persisted. The view state mechanism does not however safeguard data across different pages but is fine for remembering entered form data or a bookmark in a scrolled list across page reloads.

To keep real sessions and session variables, a `v:login` control is offered.

14.4.4. Application Code

Most VSPX controls will support XML children specifying SQL code to run at various points of the page processing cycle. The elements are:

v:before-data-bind

v:after-data-bind

v:before-post

v:before-render

These elements will have a script tag as unique child, most often containing a CDATA section for escaping the SQL text.

Additionally, most attributes of VSPX elements can have a SQL expression evaluated at initialization, pre data bind or after data bind time, as the case may be, depending on the attribute and its value. An attribute value beginning with `"--"` indicates evaluation on the initialization or the descending edge of the data bind pass. An attribute value indicating `"--after"` specifies that the value is calculated on the returning edge of recursion of the data bind pass.

Arbitrary HTML text may contain attributes with a data bound value. The attributes should be in the XHTML namespace and have a text beginning with `"--"` . The expression will be evaluated at render time, where the *control* variable refers to the enclosing VSPX template control, e.g. the page instance when at top level.

VSP Compatibility and In-Line SQL

Arbitrary HTML text may contain <?vsp ?>, <?V ?> (equivalent of <?= VSP notation) and <?U ?> (equivalent of <?/ VSP notation) processing instructions. The code in question will be evaluated during the render pass, with control set to the closest enclosing VSPX control. Please note that the <?= and <?/ VSP shortcuts cannot be used inside VSPX pages as they are not valid processing-instructions.

VSPX maintains backward compatibility with VSP through supporting the same processing instructions, but additionally requires the page source to be well formed XML. VSP pages which are well formed in XML terms will run as such under with the VSPX extension, with the addition of the `v:page` top level element.

The <?vsp ?> processing instruction expects a SQL statement. The statement can be a compound statement ending in another <?vsp ?> processing instruction at the same nesting level under the same parent tag. The other pi's <?V and <?U expect a SQL expression.

Note:

<?V ?> is not permitted inside attributes without quotation, as this is not well formed XML. When quoted, this notation in attributes has no special effect, hence the convention about the leading `"--"` and the `XHTML` namespace for HTML attributes with a computed value.

14.4.5. A Simple Example

Example 14.15. Simple VSPX Page

The fragment below shows us a VSPX page with a few labels. A label is a simple control that renders as HTML text, using a data bindable attribute to specify a value and a C printf style format string for the format. Note the use of the <?vsp ?> processing instruction. This could just as well have been an HTML literal.

```
<html>
  <body>
    <v:page name="demo_label" xmlns:v="http://example.com/vspx/">
      <p>
        <?vsp http ('<H3>Simple page to demonstrate simple VSPX controls</H3>'); ?>
      </p>
      <p> An integer <v:label name="label1" value="--(1 + 2)" format="--'%d'"/> </p>
      <p> A string <v:label name="label2" value="'123'" format="%s"/> </p>
      <p> A string with default format <v:label name="label3" value="String"/> </p>
      <p>
      An url <v:url name="url1" value="--'OpenLink Software Ltd.'" format="%s" url="--'http://openlinksw.
      <br/>
      An url (default format) <v:url name="url2" value="OpenLink Software Ltd." url="http://openlinksw.co
      </p>
      <v:include url="footer.xml"/>
    </v:page>
  </body>
</html>
```

14.4.6. VSPX Event Handler Parameters

The user-defined event handlers always accept a 'control' parameter whose type is the same as that of the control it belongs to. For example the on-post event of 'button' has a parameter 'control' of type vspx_button; after-data-bind of a 'label' has a parameter 'control' of type 'vspx_label' etc.

The event handlers for before-data-bind, after-data-bind and on-post have an additional parameter: 'e' which is of type vspx_event. The parameter ('e') keeps the HTTP request as post data, request header and path just like the global variables 'path', 'params' and 'lines' on a VSP page. In addition to that, the vspx_event (e) keeps a reference to the button pressed (if any) and a flag indicating the request type: POST or GET. It may thus be used in a complex form to detect when to trigger an event depending of event data or to directly access parameters of the HTTP request, etc.

```
create type vspx_event
as (
    ve_params any,              -- name value pairs of post data
    ve_lines  any,              -- HTTP header lines
    ve_path   any,              -- requested path , parsed as vector
    ve_button vspx_control,     -- which active control originated the event.
    ve_is_post int default 0    -- 0 for GET 1 for POST
   )  temporary self as ref
;
```

14.4.7. Registering a VSPX Event Callbacks

The event handlers mechanism can be extended with callbacks. This means registering a page method(s) which will be invoked after event scrips are processed. The page methods used in this case can be either defined using 'method' declaration inside VSPX page or using page subclass defined in code-behind script(s) (see 'code-file' below). To register a callback vc_add_handler (name, method_name) method must be invoked in any script preceding the handler stage. Parameters to the vc_add_handler are: name - name of event where callback to be executed (before-data-bind, after-data-bind, on-post, before-render), method_name - name of a page class method to be registered to the event.

```
<html>
    <body>
        <v:page name="handler_demo" xmlns:v="http://example.com/vspx/">
            <v:form name="sf" type="simple" action="form.vspx" method="POST">
                <v:text name="txt" />
                <v:button name="submit2" action="simple" value="OK" />
                <v:on-init>
```

```
                    control.vc_add_handler ('on-post', 'user_post');
                </v:on-init>
            </v:form>
            <v:method name="user_post" arglist="inout control vspx_control">
                dbg_printf ('Invoked: user post method');
            </v:method>
        </v:page>
    </body>
</html>
```

14.4.8. Commonly Used Types of Attributes of VSPX Controls

CalculateableValue

CalculateableValue — The type of attribute that contains an expression to be calculated at run time.

Description

The type of a string constant or an expression. If the value of this type is started with '--', the rest of string is the text of an expression to be calculated in order to get the effective value of the property. If the value of this type is not started with '--', the effective value is the original string itself.

The type identifier 'CalculateableValue' is introduced only for diagnostic purposes, you will never use it in VSPX code. When Virtuoso server tries to compile an invalid VSPX page, you might see a diagnostic messages like 'the value of attribute X of a control Y does not match pattern ... for type CalculateableValue'. If you see this then you should check the syntax of the value of the specified attribute.

ForcedCalculateableValue

ForcedCalculateableValue — The type of attribute that contains an expression to be calculated at run time.

Description

The type of an expression. The value of this type must be started with '--', the rest of string is the text of an expression to be calculated in order to get the effective value of the property.

The type identifier 'ForcedCalculateableValue' is introduced only for diagnostic purposes, you will never use it in VSPX code. When Virtuoso server tries to compile an invalid VSPX page, you might see a diagnostic messages like 'the value of attribute X of a control Y does not match pattern ... for type ForcedCalculateableValue'. If you see this then you should check the syntax of the value of the specified attribute.

SqlCode

SqlCode — The type of a string value that is a Text of a Virtuoso/PL procedure.

Description

Text of an event handler or other Virtuoso/PL procedure. This is expected to be a complete statement or sequence of statements, hence to be terminated like a statement, unlike the 'calculatable value' expression case.

The type identifier 'SqlCode' is introduced only for diagnostic purposes, you will never use it in VSPX code. When Virtuoso server tries to compile an invalid VSPX page, you might see a diagnostic messages like 'the value of attribute X of a control Y does not match pattern ... for type SqlCode'. If you see this then you should check the syntax of the value of the specified attribute.

SqlName

SqlName — The type of attribute that contains a name of the Virtuoso/PL UDT instance that should be created for the control.

Description

The type for a Virtuoso/PL name that should be used during code generation. KNOWN BUG: If double quotes are used in the value of this type then the generated code may be incorrect. This is why this schema restrictes the syntax of values of such type.

The type identifier 'SqlName' is introduced only for diagnostic purposes, you will never use it in VSPX code. When Virtuoso server tries to compile an invalid VSPX page, you might see a diagnostic messages like 'the value of attribute X of a control Y does not match pattern ... for type SqlName'. If you see this then you should check the syntax of the value of the specified attribute.

14.4.9. VSPX Controls

after-data-bind

after-data-bind — Container for code that should be executed after data bind.

Synopsis

```
<after-data-bind >(EventHandler)</after-data-bind >(    );
```

Description

The code contained in this element is executed after the default data bind processing on the returning edge of recursion. The context has self as the page, control as the control with this handler, event as the vspx_event which caused the page invocation. Any return value from the code is ignored.

after-data-bind-container

after-data-bind-container — This is identical to v:after-data-bind.

Synopsis

```
<after-data-bind-container >(EventHandler)</after-data-bind-container >(    );
```

Description

before-data-bind

before-data-bind — Container for code that should be executed before data bind.

Synopsis

```
<before-data-bind >(EventHandler)</before-data-bind >(    );
```

Description

The code contained in this element is executed before the default data bind processing on the descending edge of recursion. The context has self as the page, control as the control with this handler, event as the vspx_event which caused the page invocation. A return value from the code if equal to 1 (one) will stop further data-bind processing of the containing control and it's children if any.

before-data-bind-container

before-data-bind-container — This is identical to v:before-data-bind.

Synopsis

```
<before-data-bind-container >(EventHandler)</before-data-bind-container >(    );
```

Description

before-render

before-render — Container for code that should be executed before rendering.

Synopsis

```
<before-render >(EventHandler)</before-render >(    );
```

Description

The code contained in this element is executed on the descending edge of recursion when traversing the vspx control tree before rendering. This is expected to have side effects on vspx controls only, not to return anything or emit any output. Any return value from the code is ignored.

before-render-container

before-render-container — This is identical to v:before-render.

Synopsis

```
<before-render-container >(EventHandler)</before-render-container >(    );
```

Description

button

button — Scriptable button.

Synopsis

<**button** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
column (optional) ,
null-value (optional) ,
action (required) ,
value (required) ,
style (optional) ,
active (optional) ,
initial-active (optional) ,
child-window-options (optional) ,
browser-current (optional) ,
browser-filter (optional) ,
browser-list (optional) ,
browser-mode (optional) ,
browser-type (optional) ,
browser-xfer (optional) ,
selector (optional) ,
format (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Scriptable version of Submit Button of the HTML form. Depending of 'action' attribute it may have variants. In some of these variants the button will not have a submit function, as in select and browse buttons. In these cases the button will use client JavaScript to pop up new windows or for setting values in other windows.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

action. This specifies the button subclass to use.

Table 14.1. Allowed values of the 'action' attribute

simple	is a simple submit button, no special functions
submit	an alias of 'simple' button, obsolete
delete	a button for deleting a row in a data-set or data-grid control. This is represented as a submit button with a special on-post script. The delete function is performed based on table, key attributes. (check implementation!!)
browse	Button that opens pup-up window using client-side javascript (browse-button). This control allows the designer to place some part of a form's input into a pop-up window. When the HTML page is rendered, this control puts a button and associated client-side javascript into the resulting page so clicking the button opens a child window.
return	This is to be used on a page invoked for selecting from a browse button. Specifies that the value of the fields designated by the field children are to be asigned to the corresponding fields of the invoking page.
logout	This will terminate the current session when clicked. Can only occur inside the login control.

value = CalculateableValue . Text of the label of the button.

style. A style of button, affects appearance.

Table 14.2. Allowed values of the 'style' attribute

submit	This is a default style used, no special handling. The button will be rendered as a usual submit button.
url	The button will be rendered as a link, furthermore client side JavaScript code will be produced to act as submit button.
image	The button will be rendered as an image on the browser under link button. In that case value of button control must be link to the image file.

active = CalculateableValue . A data bound value to enable or disable the button. The default is '1' meaning 'enable'.

initial-active = CalculateableValue . A data bound value to enable or disable the button. The default is '1' meaning 'enable'. Unlike 'active' attribute, this one is effective only when the page is displayed in the first time, not after user posts data back to the page.

child-window-options. Options for oppening a child pop-up window.This can be used only in conjuction with action browse.

browser-current. Current directory of browsing. Can be used only with browse button for WebDAV or File system resources.

browser-filter. Filter expression(s) for browsing. (see above)

browser-list. Type of browser list, 0 - short, 1 - long

browser-mode. COL, RES or STANDALONE , for a file system or DAV browse button, this specifies whether to return an path name or internal ID.

browser-type. This designates the type of browser: dav or OS (filesystem).

browser-xfer. For a browse button, this is the means of transferring the data between windows, DOM is default. No other options in current implementation.

selector. For a browse button this is the URL that will be loaded into the pop up window.

format = CalculateableValue . A sprintf format string for printing the value

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_button

Button class, encapsulate all controls originating a event

```
create type vspx_button under vspx_field as
(
  bt_pressed int default 0,
  bt_style  varchar default 'submit',
  bt_close_img varchar,
  bt_open_img varchar,
  bt_url varchar default '',
  bt_l_pars varchar default '',
  bt_text varchar default '',
  bt_anchor int default 0
)  temporary self as ref
overriding method vc_render () returns any,
overriding method vc_xrender () returns any,
overriding method vc_set_model () returns any,
constructor method vspx_button (name varchar, parent vspx_control)
```

Examples

Example 14.16. Buton shown as an image

The button of the form will be shown as a picture plus.gif. Attributes whose names start with 'xhtml_' are placed into the resulting HTML with no changes.

```
<v:page name="button__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:button</title>
    </head>
    <body>
      <v:form name="form1" type="simple" action="" method="POST">
        <v:text name="txt1" default=""/>
        <v:button name="submit1" action="simple" style="image" xhtml_alt="A test button" value="--'plus.g
      </v:form>
    </body>
  </html>
</v:page>
```

Example 14.17. Simple 'Add-Number' example

The form accepts two numbers and calculates their sum.

```
<v:page name="button__1" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:button</title>
    </head>
    <body>
      <v:form name="f1" type="simple" action="" method="POST">
        <v:label name="l1" value="--0" format="%.2f" /><br/>
        <v:text name="t1" default="0"/>
        <v:text name="t2" default="0"/>
        <v:button name="b1" action="simple" value="Add" >
        <v:on-post>
         self.l1.ufl_value := atof (self.t1.ufl_value) + atof (self.t2.ufl_value);
        </v:on-post>
        </v:button>
      </v:form>
    </body>
  </html>
</v:page>
```

Example 14.18. Simple 'Browse File' dialog

The form allows to select a file from server's file system <html> <body>

```
<v:page name="browse__2" xmlns:v="http://http://example.com/vspx/">
  <v:form name="f1" type="simple" method="POST">
      <v:text name="floc" value="" xhtml_size="60%" />
      <v:button action='browse' name="cmb" selector="browser/dav_browser.vsp"
                child-window-options="resizable=yes, status=no, menubar=no, scrollbars=no, width=640, hei
                value="Browse"
                browser-type="os"
                browser-mode="RES"
                browser-xfer="DOM"
                browser-list="1"
                browser-current="1"
                browser-filter="*">
        <v:field name="floc" />
      </v:button>
  </v:form>
</v:page>
</body>
</html>
```

Example 14.19. Simple browse button example

The form allows to select a two values from a different page <html> <body>

```
<v:page name="button__3" xmlns:v="http://http://example.com/vspx/">
  <v:form name="frm" type="simple" method="POST">
      <v:text name="fld1" value="" />
      <v:text name="fld2" value="" />
      <v:button action='browse' name="br1" selector="button__4.vspx"
                child-window-options="scrollbars=yes, menubar=no, height=630, width=600"
                value="Browse">
        <v:field name="fld1" />
        <v:field name="fld2" />
      </v:button>
  </v:form>
</v:page>
```

```
</body>
</html>
```

Example 14.20. Simple select button example

The form returns back to caller form two walues from a text box and select list <html> <body>

```
<v:page name="button__4" xmlns:v="http://http://example.com/vspx/">
  <v:form name="f1" type="simple" method="POST">
     <v:text name="sl1" value="Test" />
     <v:select-list name="sl2">
       <v:item name="*default*" value="0" />
       <v:item name="FIRST"     value="1" />
       <v:item name="SECOND"    value="2" />
     </v:select-list>
        <v:button name="select1" action="return" value="Select">
          <v:field name="fld1" ref="sl1" />
          <v:field name="fld2" ref="sl2" />
        </v:button>
 </v:form>
</v:page>
</body>
</html>
```

calendar

calendar — Databound calendar control.

Synopsis

<**calendar** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
initial-date (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This is the generic calendar control.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

initial-date = CalculateableValue . Expression which returns a date for setting initially the current date of the calendar.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_calendar

```
create type vspx_calendar under vspx_control as
(
  cal_date date,
  cal_meta any,
  cal_selected datetime,
  cal_current_row vspx_row_template
) temporary self as ref
method vc_get_date_array () returns any,
overriding method vc_view_state (stream any, n int) returns any,
overriding method vc_set_view_state (e vspx_event) returns any,
constructor method vspx_calendar (name varchar, parent vspx_control)
```

Examples

Example 14.21. A calendar

This demo will show a calendar allowing to list dates by months:

```
<v:page name="pagecal1" xmlns:v="http://http://example.com/vspx/">
<html>
<body>
<v:form name="form1" type="simple" method="POST" >
    <v:calendar name="cal1" initial-date="--now()">
      <v:template type="simple" name="chead1" name-to-remove="table" set-to-remove="bottom">
      <table border="0" cellpadding="0" cellspacing="0">
        <tr>
         <td align="center">
          <v:button name="pmon" value="<" action="simple" style="url">
            <v:on-post>
            self.cal1.cal_date := dateadd ('month', -1, self.cal1.cal_date);
            self.cal1.vc_data_bind (e);
            </v:on-post>
          </v:button>
         </td>
         <td colspan="5" align="center">
           <?V monthname((control.vc_parent as vspx_calendar).cal_date) ?>
           <?V year((control.vc_parent as vspx_calendar).cal_date) ?>
         </td>
         <td align="center">
          <v:button name="nmon" value=">" action="simple" style="url">
            <v:on-post>
            self.cal1.cal_date := dateadd ('month', 1, self.cal1.cal_date);
            self.cal1.vc_data_bind (e);
            </v:on-post>
          </v:button>
         </td>
         </tr>
        <tr><td>Sun</td><td>|Mon</td><td>|Tue</td><td>|Wed</td><td>|Thu</td><td>|Fri</td><td>|Sat</td></t
      </table>
      </v:template>
      <v:template type="repeat" name="cbody1" name-to-remove="" set-to-remove="">
      <v:template type="browse" name="crow1" name-to-remove="table" set-to-remove="both">
      <table>
      <tr>
       <td align="center"><v:button style="url" action="simple" name="b1" value="--cal_icell(control, 0)"
       <td align="center"><v:button style="url" action="simple" name="b2" value="--cal_icell(control, 1)"
       <td align="center"><v:button style="url" action="simple" name="b3" value="--cal_icell(control, 2)"
       <td align="center"><v:button style="url" action="simple" name="b4" value="--cal_icell(control, 3)"
       <td align="center"><v:button style="url" action="simple" name="b5" value="--cal_icell(control, 4)"
       <td align="center"><v:button style="url" action="simple" name="b6" value="--cal_icell(control, 5)"
       <td align="center"><v:button style="url" action="simple" name="b7" value="--cal_icell(control, 6)"
      </tr>
```

```
        </table>
        </v:template>
        </v:template>
        <v:template type="simple" name="cbott1" name-to-remove="table" set-to-remove="top">
        <table>
        </table>
        </v:template>
      </v:calendar>
</v:form>
</body>
</html>
</v:page>
```

check-box

check-box — Scriptable check-box.

Synopsis

<**check-box** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
column (optional) ,
null-value (optional) ,
error-glyph (optional) ,
auto-submit (optional) ,
value (optional) ,
element-value (optional) ,
element-place (optional) ,
element-path (optional) ,
element-params (optional) ,
element-update-path (optional) ,
element-update-params (optional) ,
fmt-function (optional) ,
cvt-function (optional) ,
group-name (optional) ,
initial-checked (optional) ,
is-boolean (optional) ,
true-value (optional) ,
false-value (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

is a represantation of HTML check box. Scriptable, databindable.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

error-glyph. The character to be displayed near the resulting HTML input element if the test of v:validator of the element detects an error in the current value of the element.

auto-submit. Flag to auto submit the parent form if value of the control is changed.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in

ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

group-name = SqlName . When several check boxes are grouped, this is the group name. This will be submitted instead of the control name on post.

initial-checked = CalculateableValue . Specifies whether the control is initially checked.

is-boolean. If this attribute is set to '1' then the check-box is forced to ignore its 'initial-checked' status and work using the data-bound value as the only criterion for enabling or disabling its 'checked' property. This mode is convenient for editing two-state data values. Before render, the control will check if the ufl_value is equal to 'true-value' or 'false-value', and it is displayed as checked if the ufl_value is equal to 'true-value' (or it is not equal to any of these two but is not a logical 'false'). On post, a new status of the checkbox is inspected, and the ufl_value is set to 'true-value' if it is checked or 'false-value' otherwise. The default value of this attribute is '0' meaning that there is no system-level relation between the 'checked' status and the 'value'. When the form with the check-box submits data, the submitted value of the attribute depends on its 'is-boolean' property. If it's '0' then the result of cast (control.ufl_value as varchar) is submitted; otherwise a string '1' is submitted.

true-value = CalculateableValue . This attribute should be used if and only if 'is-boolean' attribute is set to '1'. The calculated value of this attribute is saved in ufl_true_value field of the control and is used to represent a logical 'true' for the control. The checkbox is displayed as checked if the bound value is equal to the ufl_true_value. If the checked checkbox is submitted then the bound value of the control is set to the ufl_true_value.

false-value = CalculateableValue . This attribute should be used if and only if 'is-boolean' attribute is set to '1'. The calculated value of this attribute is saved in ufl_false_value field of the control and is used to represent a logical 'false' for the control. The checkbox is displayed as not checked if the bound value is equal to the ufl_valuse_value. If no checked checkbox is submitted by a form then the bound value of the control is set to ufl_false_value.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_check_box

```
create type vspx_check_box under vspx_field
temporary self as ref
constructor method vspx_check_box (name varchar, parent vspx_control),
overriding method vc_render () returns any,
overriding method vc_xrender () returns any,
overriding method vc_view_state (stream any, n int) returns any,
overriding method vc_set_view_state (e vspx_event) returns any,
overriding method vc_set_model () returns any
```

Examples

Example 14.22. Entry form with a checkbox

Depending on the state of the checkbox, the submitted value is either 'checked' or 'unchecked'.

```
<v:page name="check_box__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:check-box</title>
    </head>
    <body>
      <v:form name="form1" type="simple" action="" method="POST">
        <v:check-box name="cb1" initial-checked="0" value="-- case control.ufl_selected when 1 then 'chec
        <v:button name="submit1" action="simple" value="OK"/>
      </v:form>
    </body>
  </html>
</v:page>
```

VX-S-2

code-file

code-file — Code-behind file containing SQL script.

Synopsis

<**code-file** /> (*url* (required) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This element is used to load an external SQL script after page class compilation and before page execution. This script may contain page subclass or custom control definitions. In this way SQL code can be separated from VSPX markup, or in other words to separate page design from application logic.

Attributes

url. URL of file to be loaded after VSPX page compilation. If relative then the base is the page where the control resides (i.e. same URL resolution rules applied as for includes).

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Examples

Example 14.23. Code-behind SQL script

The script of a button's post event is in separate SQL file.

The code_file__0.sql contents is:

```
drop type my_page_subclass
;

create type my_page_subclass under DB.dba.page__vspx_code__file____0_vspx
temporary self as ref
overriding method vc_post_b1 (control vspx_button, e vspx_event) returns any,
method button_change (control vspx_button) returns any
;

create method vc_post_b1 (inout control vspx_button, inout e vspx_event) for my_page_subclass
 {
   if (not control.vc_focus) return;
   self.button_change (control);
   return;
 }
;

create method button_change (inout control vspx_button) for my_page_subclass
 {
   self.var1 := self.var1 + 1;
   control.ufl_value := 'Activated';
 }
;

<v:page name="page1" xmlns:v="http://http://example.com/vspx/" page-subclass="my_page_subclass">
  <html>
```

```
    <body>
      <v:code-file  url="code_file__0.sql"/>
      <v:variable name="var1" type="int" default="0" param-name="id" persist="pagestate" />
      <v:form type="simple" name="f1">
        <v:label name="l1" value="--self.var1" format="%d" />
        <v:button action="simple" name="b1" value="Submit" />
      </v:form>
    </body>
  </html>
</v:page>
```

column

column — A column marker.

Synopsis

<**column** /> (*name* (required) ,
label (optional) ,
input-format (optional) ,
output-format (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

A column marker for use in v:data-set, v:data-grid and v:data-source. This element should exist for each selected column of the SQL expression of the data set. If this is specified under data-set, data-source or data-grid controls, this must be the exact same columns as in SQL statement to be evaluated. If those element is omitted in data-set or data-grid, the columns will be extracted from compilation of the SQL statement. However, this will always be required for calls of stored procedures that return resultsets and for the data-source control.

Attributes

name = SqlName . The name of column

label = CalculateableValue . Alternate text which could be used to display in column headings.

input-format. A sprintf format string for printing the input value

output-format. A sprintf format string for printing the output value

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

data-grid

data-grid — Scrollable databound multi-row control.

Synopsis

```
<data-grid /> (   name (required) ,
                  annotation (optional) ,
                  initial-enable (optional) ,
                  enabled (optional) ,
                  instantiate (optional) ,
                  control-udt (optional) ,
                  xsd-stub-xhtml (optional) ,
                  width (optional) ,
                  height (optional) ,
                  data (optional) ,
                  meta (optional) ,
                  nrows (optional) ,
                  sql (required) ,
                  scrollable (optional) ,
                  cursor-type (optional) ,
                  edit (optional) ,
                  debug-srcfile (optional) ,
                  debug-srcline (optional) ,
                  debug-log (optional) ) ;
```

Description

This is the generic multi-row database view control. It is used to show repeating data, as from tables or procedure views. Allows scrolling (paging) editing the data; adding a row or removal of existing rows. Usually this control generates a PL scrollable cursor of type as specified. The number of rows shown are configurable via nrows attribute. Note also that column children elements are optional; they can be omitted so then VSPX engine will compute them from specified SQL statement in 'sql' attribute. Specific to this control is to have row-template and frame-template, these are to present repeating and non-repeating groups of children elements. The frame-template will usually have a 'rowset' placeholder to designate the place where repeating group (row-template) will be instantiated. The control expects to find child controls with specific names. for scrolling buttons - [data-grid name]'_prev' and [data-grid name]'_next'; for editing buttons - [data-grid name]'_edit' and [data-grid name]'_delete'.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

data = CalculateableValue . Expression which returns an array of rowset data, this is an alternative to specifying an SQL expression. The result then will be used to instantiate the repeating group. An example of such data is the result returned by 'exec' function:

```
(
  ("ALFKI" "Alfreds Futterkiste" "030-0074321" )
  ("ANATR" "Ana Trujillo Emparedados y helados" "(5) 555-4729" )
)
```

meta = CalculateableValue . This works with combination of data attribute, this expression must return an array of ro metadata. So when this is specified it needs to be an expression returning meta-data for columns. In practice this is the same as 1st element of metadata returned by 'exec()' :

```
(
  ("CustomerID" 182 0 5 0 1 1 "Demo" "CustomerID" "demo" "Customers" 0 )
  ("CompanyName" 182 0 40 1 1 1 "Demo" "CompanyName" "demo" "Customers" 0 )
  ("Phone" 182 0 24 1 1 1 "Demo" "Phone" "demo" "Customers" 0 )
)
```

for details of metadata see 'exec()' function description.

nrows = CalculateableValue . The maximum number of replicas of the row template to be made for rows selected. This is like the rowset size for a scrollable cursor.

sql = SqlCode . The select statement that gets the data. Parameters to the statement MUST be specified as SQL identifiers prefixed with a colon (named parameter). The values are given in the control's vspx:param children. These specify the parameter name and a data bound expression for the value.

scrollable. The setting controls whether next and previous page buttons are presented. This can be on even if the cursor is not scrollable as such.

cursor-type.

Table 14.3. Allowed values of the 'cursor-type' attribute

static	A static cursor is used.
dynamic	A dynamic cursor is used.
keyset	A keyset cursor is used.

edit = CalculateableValue . Flags whether editing features are enabled on data grid control

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_data_grid

Scrollable, Multi-Row data grid Class

```
create type vspx_data_grid under vspx_form
as (
    dg_nrows int default -1,    -- how many rows to show on single page
    dg_scrollable int default 0,  -- scroll on form is enabled
    dg_editable int default 1,          -- disable edit/add on whole grid
    dg_row_meta any,      -- metadata
    dg_row_data any,      -- the data for procedure binding
    dg_current_row vspx_row_template,   -- current row template
    dg_rowno_edit int default null, -- last edited row in result set, to re-display the edit box on error
    dg_rows_fetched int default 0,  -- these are to keep state for scrolling
    dg_prev_bookmark any default null,
    dg_last_bookmark any default null
   )  temporary self as ref
  method vc_templates_clean () returns any,
  constructor method vspx_data_grid (name varchar, parent vspx_control),
  overriding method vc_set_view_state (e vspx_event) returns any,
  overriding method vc_view_state (stream any, n int) returns any
```

Examples

Example 14.24. Editable multi-row data grid based on data-grid control

This example will show a list of customers from the Northwind demo database. Allows editing, addtion and removal of existing records:

```
<v:page name="data_grid__0" xmlns:v="http://http://example.com/vspx/">
<html>
  <body>
      <v:data-grid name="dg" nrows="5" sql="select CustomerID, CompanyName, Phone from Demo.demo.Customer
        <v:param name="mask" value="'%'"/>
        <v:template name="t1" type="frame">
          <div>
            <div>
              Action
                <v:label name="l1" value="--(control.vc_parent as vspx_data_grid).dg_row_meta[0]"/>
              <v:label name="l2" value="--(control.vc_parent as vspx_data_grid).dg_row_meta[1]"/>
              <v:label name="l3" value="--(control.vc_parent as vspx_data_grid).dg_row_meta[2]"/>
            </div>
            <v:rowset/>
            <v:form type="add"/>
            <div>
              <v:button name="dg_prev" action="simple" value="&lt;&lt;"/>
              <v:button name="dg_next" action="simple" value="&gt;&gt;"/>
            </div>
          </div>
        </v:template>
        <v:template name="t2" type="row">
          <div>
            <v:button name="dg_edit" action="simple" value="Edit"/>
            <v:button name="dg_delete" action="simple" value="Delete">
              <v:on-post>
              delete from Demo.demo.Customers where CustomerID = self.dg.dg_current_row.te_rowset[0];
              self.dg.vc_data_bind (e);
                </v:on-post>
            </v:button>
            <v:label name="label1" value="--(control.vc_parent as vspx_row_template).te_rowset[0]"/>
            <v:label name="label2" value="--(control.vc_parent as vspx_row_template).te_rowset[1]"/>
            <v:label name="label3" value="--(control.vc_parent as vspx_row_template).te_rowset[2]"/>
          </div>
        </v:template>
        <v:template name="t3" type="if-not-exists">
          <div>No rows selected</div>
        </v:template>
        <v:template name="t4" type="edit">
          <v:form name="u1" type="update" table="Demo.demo.Customers" if-not-exists="insert">
            <v:key column="CustomerID" value="--self.dg.dg_current_row.te_rowset[0]" default="null"/>
            <v:template type="if-exists" name="t5">
```

```
            <div>
              <v:button name="b1" action="submit" value="Update"/>
              <input type="submit" name="b2" value="Cancel"/>
              <v:text name="c_id1" column="CustomerID"/>
              <v:text name="c_name1" column="CompanyName"/>
              <v:text name="c_phone1" column="Phone"/>
            </div>
          </v:template>
        </v:form>
      </v:template>
      <v:template name="t6" type="add">
        <v:form type="update" name="a1" table="Demo.demo.Customers" if-not-exists="insert">
          <v:key column="CustomerID" value="--''" default="null"/>
          <v:template name="t7" type="if-exists">
            <v:button name="b3" action="submit" value="Add"/>
            <v:text name="c_id2" column="CustomerID"/>
            <v:text name="c_name2" column="CompanyName"/>
            <v:text name="c_phone2" column="Phone"/>
          </v:template>
        </v:form>
      </v:template>
    </v:data-grid>
  </body>
</html>
</v:page>
```

data-list

data-list — Select list initialized from database table.

Description

This control is used to make a select list, based on a SQL expression. Also instead of SQL expression only table name could be given, so then control will compose apropriate select statement.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

error-glyph. The character to be displayed near the resulting HTML input element if the test of v:validator of the element detects an error in the current value of the element.

auto-submit. Flag to auto submit the parent form if value of the control is changed.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

table. A table name for select statement.

key-column = SqlName . A key column name.

value-column = SqlName . A value column name.

sql = CalculateableValue . An alterantive of 'table' attribute, when this attribute is specified it must contains a valid select statement. The selection list will be instantiated using a cursor as this expression is defined.

defvalue = CalculateableValue . A default value for the control.

multiple. Used to desigante a multiple selection list box. In this case the control's value will be an array of key data of selected items.

list-document = CalculateableValue . This is to obtain all or some of items of the select-list from an XML document. If this attribute is specified then the value of the calculated attribute should be an XML entity and this entity will be saved in vsl_list_document field of the control; values of 'list-match', 'list-key-path' and 'list-value-path' arguments should specify XQuery expressions that should be used to retrieve keys and displayable values of items. All selection items composed from the value of 'list-document' will be listed before all items from 'table' or 'sql', if both methods of data retrieval are used.

list-match = CalculateableValue . This is to calculate a string value that is an XQuery expression. The text of this expression will be saved in 'vsl_list_match' member of the control. This expression will be used during data binding to get array of displayable items from the value of 'list-document'. The expression should return a node-set using 'list-document' entity as a context mode; every item of the node-set will be converted into list item via 'list-key-path' and 'list-value-path' expressions.

list-key-path = CalculateableValue . This is to specify the XQuery expression that calculates key value of a list item, using a result of 'list-match' as a context node. The text of the expression will be saved in 'vsl_list_key_path' member of the control.

list-value-path = CalculateableValue . This is to specify the XQuery expression that calculates a displayable value of a list item, using a result of 'list-match' as a context node. The text of the expression will be saved in 'vsl_list_value_path' member of the control.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_data_list

```
create type vspx_data_list under vspx_select_list temporary self as ref
constructor method vspx_data_list (name varchar, parent vspx_control)
```

Examples

Example 14.25. Select list based on table source

This example will render in a form a select list containing the customers from Northwind demo database with a option values their customer IDs.

```
<v:page name="data_list__0" xmlns:v="http://http://example.com/vspx/">
<html>
  <body>
      <v:form name="f1" type="simple" method="POST">
        <v:data-list name="dl1" table="Demo.demo.Customers" key-column="CustomerID" value-column="Company
      </v:form>
  </body>
</html>
</v:page>
```

Example 14.26. Select list based on SQL select statement

This example will render in a form a select list containing the customers from Northwind demo database with a option values their customer IDs.

```
<v:page name="data_list__1" xmlns:v="http://http://example.com/vspx/">
<html>
  <body>
      <v:form name="f1" type="simple" method="POST">
        <v:data-list name="dl1" sql="select * from Demo.demo.Customers" key-column="CustomerID" value-col
      </v:form>
  </body>
</html>
</v:page>
```

data-set

data-set — Scrollable, multi-row data bound grid.

Synopsis

<**data-set** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
sql (optional) ,
data-source (optional) ,
data (optional) ,
meta (optional) ,
nrows (optional) ,
scrollable (required) ,
cursor-type (optional) ,
edit (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

A container for displaying and/or editing the content of a resultset. This is the generic multi-row database view control. It is used to show repeating data, as from tables or procedure views. Allows scrolling (paging) editing the data; adding a row or removal of existing rows. Usually this control generates a PL scrollable cursor of type. The number of rows shown is configurable via nrows attribute. Note also that column children elements are optional; they can be omitted so then VSPX engine will compute them from the specified SQL statement in 'sql' attribute. This control has the same functionality as the data-grid control but has different syntax, better suited for editing via plugins for 3-d party WYSWYG HTML authoring tools (as Addobe GoLive and similar). Specific to this control is to have several templates to present repeating and non-repeating groups of children elements. These templates are as follows: two generic templates to represent header and footer sections and one repeating template to enclose edit, add, not-exists and row (browse) sections. All of those templates are optional and their usage can be seen in examples. Also following the convention for names of controls must be followed: for scrolling buttons - [data-set name]'_prev', [data-set name]'_next', [data-set name]'_first' and [data-set name]'_last'; for editing buttons - [data-set name]'_edit' and [data-set name]'_delete'.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

sql = SqlCode . The select statement that gets the data. Parameters to the statement MUST be specified as SQL identifiers prefixed with a colon. The values are given in the control's vspx:param children. These specify the parameter name and a data bound expression for the value.

data-source = SqlName . A reference to a data-source, which wil lbe used to bind the data in data-set grid.

data = CalculateableValue . When this attribute is specified it must be an expression returning array of arrays. This is an alternative to specifying an SQL expression or data-source. The result then will be used to instantiate the repeating group. An example of such data is the result returned by 'exec' function:

```
(
  ("ALFKI" "Alfreds Futterkiste" "030-0074321" )
  ("ANATR" "Ana Trujillo Emparedados y helados" "(5) 555-4729" )
)
```

meta = CalculateableValue . This attribute is used together with 'data', so when is specified it needs to be an expression returning a meta-data for columns corresponding to the these returned by 'data' expression. In practice it's same as 1-st element of metadata returned by 'exec()' :

```
(
  ("CustomerID" 182 0 5 0 1 1 "Demo" "CustomerID" "demo" "Customers" 0 )
  ("CompanyName" 182 0 40 1 1 1 "Demo" "CompanyName" "demo" "Customers" 0 )
  ("Phone" 182 0 24 1 1 1 "Demo" "Phone" "demo" "Customers" 0 )
)
```

for details of metadata see 'exec()' function description.

nrows = CalculateableValue . The maximum number of replicas of the row template to be made for rows selected. It is like the rowset size for a scrollable cursor.

scrollable. The setting controls whether next and previous page buttons are presented. This can be on even if the cursor is not scrollable as such.

cursor-type.

Table 14.4. Allowed values of the 'cursor-type' attribute

static	A static cursor is used.
dynamic	A dynamic cursor is used.
keyset	A keyset cursor is used.

edit. Flags whether editing features are enabled on data grid control

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_data_set

```
create type vspx_data_set under vspx_form
as (
    ds_nrows int,     -- how many rows to show on single page
    ds_scrollable int,      -- scroll on form is enabled
    ds_editable int default 1,          -- disable edit/add on whole grid
    ds_row_meta any,      -- metadata
    ds_row_data any,      -- data coming from a function, rowset
    ds_current_row vspx_row_template,   -- current row template
    ds_rowno_edit int default null, -- last edited row in result set, to re-display the edit box on error
    ds_rows_fetched int default 0,  -- how many rows are fetched for current page
    ds_rows_total int default 0,  -- how many data rows do we have in total (for vector)
    ds_rows_offs    int default 0,  -- this is the zero-based index of the first row of the current page
    ds_rows_offs_saved int default 0,  -- this is the value of ds_rows_offs that was saved in the page st
    ds_scrolled     int default 0,
    ds_has_next_page int default 0,     -- Flag if there are rows after the current page (so 'next page'
    ds_prev_bookmark any default null, -- Bookmark of the record that was at the beginning of previous re
    ds_last_bookmark any default null, -- Bookmark of the record that was at the end of previous retrieva
    ds_rows_cache any,
    ds_data_source vspx_data_source default null
   )  temporary self as ref
  method vc_templates_clean () returns any,
  method vc_reset () returns any,
  method ds_column_offset (name varchar) returns any,
  method ds_iterate_rows (inx int) returns any,
  constructor method vspx_data_set (name varchar, parent vspx_control),
  overriding method vc_set_view_state (e vspx_event) returns any,
  overriding method vc_view_state (stream any, n int) returns any
```

Examples

Example 14.27. Editable multi-row data grid based on data-set control

This example will show a list of customers from the Northwind demo database. Allows editing, addtion and removal of existing records.

```
<v:page name="data_set__0" xmlns:v="http://http://example.com/vspx/">
<html>
  <body>
      <v:data-set name="ds" sql="select CustomerID, CompanyName, Phone from Demo.demo.Customers" nrows="1
        <v:template name="t1" type="simple">
          <div>
            Action
            <v:label name="l1" value="CustomerID" format="%s" width="80"/>
            <v:label name="l2" value="CompanyName" format="%s" width="80"/>
            <v:label name="l3" value="Phone" format="%s" width="80"/>
          </div>
        </v:template>
        <v:template name="t2" type="repeat">
          <v:template name="t7" type="if-not-exists">
            <div>No rows selected</div>
          </v:template>
          <v:template name="t5" type="edit">
            <v:form name="u1" type="update" table="Demo.demo.Customers" if-not-exists="insert">
              <v:key column="CustomerID" value="--self.ds.ds_current_row.te_rowset[0]" default="null"/>
              <v:template name="template6" type="simple">
                <div>
                  <v:button name="upd_button" action="submit" value="Update"/>
                  <input type="submit" name="ds_cancel" value="Cancel"/>
                  <v:text name="c_id1" column="CustomerID"/>
                  <v:text name="c_name1" column="CompanyName"/>
                  <v:text name="c_phone1" column="Phone"/>
                </div>
```

```
            </v:template>
          </v:form>
        </v:template>
        <v:template name="t8" type="add">
          <v:form name="a1" type="update" table="Demo.demo.Customers" if-not-exists="insert">
            <v:key column="CustomerID" value="--''" default="null"/>
            <v:template name="template9" type="simple">
              <div>
                <v:button name="add_button" action="submit" value="Add"/>
                <v:text name="c_id2" column="CustomerID"/>
                <v:text name="c_name2" column="CompanyName"/>
                <v:text name="c_phone2" column="Phone"/>
              </div>
            </v:template>
          </v:form>
        </v:template>
        <v:template name="t4" type="browse">
          <div>
            <v:button name="ds_edit" action="simple" value="Edit"/>
            <v:button name="ds_delete" action="simple" value="Delete">
              <v:on-post>
                    delete from Demo.demo.Customers where CustomerID = self.ds.ds_current_row.te_rowset
                    self.ds.vc_data_bind(e);
                </v:on-post>
            </v:button>
            <v:label name="l5" value="--(control.vc_parent as vspx_row_template).te_rowset[0]"/>
            <v:label name="l6" value="--(control.vc_parent as vspx_row_template).te_rowset[1]"/>
            <v:label name="l7" value="--(control.vc_parent as vspx_row_template).te_rowset[2]"/>
          </div>
        </v:template>
      </v:template>
      <v:template name="t3" type="simple">
        <div>
          <v:button name="ds_prev" action="simple" value="&lt;&lt;"/>
          <v:button name="ds_next" action="simple" value="&gt;&gt;"/>
        </div>
      </v:template>
    </v:data-set>
  </body>
</html>
</v:page>
```

Example 14.28. Simple multi-row data grid based on data-set control

This example will show a list of customers from the Northwind demo database. Allows scrolling only of existing records.

```
<v:page name="data_set__0" xmlns:v="http://http://example.com/vspx/">
<html>
  <body>
      <v:data-set name="ds" sql="select CustomerID, CompanyName, Phone from Demo.demo.Customers" nrows="1
        <v:template name="t1" type="simple">
          <div>
            <v:label name="l1" value="CustomerID" format="%s" width="80"/>
            <v:label name="l2" value="CompanyName" format="%s" width="80"/>
            <v:label name="l3" value="Phone" format="%s" width="80"/>
          </div>
        </v:template>
        <v:template name="t2" type="repeat">
          <v:template name="t7" type="if-not-exists">
            <div>No rows selected</div>
          </v:template>
          <v:template name="t4" type="browse">
            <div>
              <v:label name="l5" value="--(control.vc_parent as vspx_row_template).te_rowset[0]"/>
              <v:label name="l6" value="--(control.vc_parent as vspx_row_template).te_rowset[1]"/>
              <v:label name="l7" value="--(control.vc_parent as vspx_row_template).te_rowset[2]"/>
            </div>
          </v:template>
        </v:template>
        <v:template name="t3" type="simple">
```

```
            <div>
              <v:button name="ds_prev" action="simple" value="&lt;&lt;"/>
              <v:button name="ds_next" action="simple" value="&gt;&gt;"/>
            </div>
          </v:template>
        </v:data-set>
  </body>
</html>
</v:page>
```

data-source

data-source — Scrollable multi-row data bound source.

Synopsis

<**data-source** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
expression-type (required) ,
nrows (optional) ,
initial-offset (optional) ,
data (optional) ,
meta (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Invisible multi-row data source. This control is an invisible represantation of a result set. Also it offer a number of methods for accessing and updating the data. It can be used as a source in the data-set control or as a separate data source for various form controls (such as label, url etc.). This control is using 'SELECT TOP N,M ..' statements to bind the data into the resultset (when source is a table or SQL statement), hence this should be taken into account when using it.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

expression-type. Denotes the type of 'expression'

Table 14.5. Allowed values of the 'expression-type' attribute

SQL	The expression is a SQL select statement
TABLE	The expression is a table reference
PROCEDURE	The expression is a procedure call
ARRAY	The rowset is already prepared and supplied as an array of arrays

nrows = CalculateableValue . The maximum number of rows to be selected. It is like the rowset size for a scrollable cursor.

initial-offset = CalculateableValue . Number of record to start data binding of rowset

data = CalculateableValue . When this attribute is specified it must be an expression returning array of arrays. This is an alternative to specifying an SQL expression or data-source. The result then will be used to instantiate the repeating group. An example of such data is the result returned by 'exec' function:

```
(
  ("ALFKI" "Alfreds Futterkiste" "030-0074321" )
  ("ANATR" "Ana Trujillo Emparedados y helados" "(5) 555-4729" )
)
```

meta = CalculateableValue . This attribute is used together with 'data', so when is specified it needs to be an expression returning a meta-data for columns corresponding to the these returned by 'data' expression. In practice it's same as 1-st element of metadata returned by 'exec()' :

```
(
  ("CustomerID" 182 0 5 0 1 1 "Demo" "CustomerID" "demo" "Customers" 0 )
  ("CompanyName" 182 0 40 1 1 1 "Demo" "CompanyName" "demo" "Customers" 0 )
  ("Phone" 182 0 24 1 1 1 "Demo" "Phone" "demo" "Customers" 0 )
)
```

for details of metadata see 'exec()' function description.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_data_source

```
create type vspx_data_source under vspx_control
as    (
    ds_row_meta any,      -- metadata
    ds_row_data any,      -- data coming from a function, rowset

Examples

Example 14.29. Simple navigation form using invisible data-source control

This example will show a cell of the customers table from the Northwind demo database. Allows to show different columns : name and phone.

```
<v:page name="data_source__0" xmlns:v="http://http://example.com/vspx/">
<html>
<body>
<v:variable name="offset" default="0" type="int"/>
   <v:form name="f1" method="POST" type="simple">
   <div>There is a hidden data-source on "<?V self.datasource1.ds_sql ?>"</div>
   <v:data-source name="datasource1" expression-type="sql" nrows="10" initial-offset="--self.offset">
     <v:expression>
```

```
        select * from Demo.demo.Customers where CustomerID like ? order by CompanyName desc
      </v:expression>
      <v:param name="mask" value="--('L%')"/>
      <v:column name="CompanyName" label="Company Name" input-format="%s" output-format="%s"/>
      <v:column name="Phone" label="Telephone" input-format="%s" output-format="%s" />
    </v:data-source>
    <div>
    row #: <v:text name="r1" value="0" /><br />
    col #: <v:text name="c1" value="0" /><br />
    Seek : <v:button action="simple" name="b1" value="OK" />
    </div>
    <div>
    "<v:label name="l1" value="--self.datasource1.get_column_label (atoi(self.c1.ufl_value))" />" =
    <v:label name="l2" value="--self.datasource1.get_item_value (atoi(self.r1.ufl_value),atoi(self.c1.ufl_
    </div>
     <v:on-post>
       self.l1.vc_data_bind (e);
       self.l2.vc_data_bind (e);
     </v:on-post>
    </v:form>
</body>
</html>
</v:page>
```

error-summary

error-summary — Placeholder for error messages.

Synopsis

<**error-summary** /> (*match* (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Placeholder for form error messages. This is used on a form to mark where error messages resulting from field or form validation are to be placed. This will be rendered if the vc_is_valid member of the enclosing page is false. If rendered, this prints an error message generated by a validator or a catch handler. This control wiil not be instantiated. The error-summary may show errors for all controls or for a group of controls whose name matches a given regular expression. The vc_error_message members of all controls whose validation failed will be shown at the place marked by this control if attribute 'match' is not specified. Otherwise the vc_error_message of controls whose validation failed and 'name' matches the pattern specified will be shown.

Attributes

match. This attribute specifies a regular expression to be matched against names of controls with failed validation. The expression may match more than one control name, concatenating the messages in document order of controls. In this way an error summary may appear in different places of the page to print errors for different controls.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Examples

Example 14.30. Validation of text area input

The form contains two v:textarea controls with v:validator elements inside. When the OK button is pressed data are posted back to the same URI so the page is instantiated again. If any validator found a violation the message is shown to the user in the place specified by v:error-summary element.

```
<v:page name="error_summary__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:error-summary</title>
    </head>
    <body>
      <v:error-summary />
      <v:form name="form1" type="simple" action="" method="POST">
        <v:textarea name="ta1" default="enter your first text here" value="--coalesce ({?'ta1'}, control.
          <v:validator test="length" min="0" max="50" message="The length of the first input should not e
        </v:textarea>
        <v:textarea name="ta2" default="enter your second text here" value="--coalesce ({?'ta1'}, control
          <v:validator test="length" min="0" max="50" message="The length of the second input should not
        </v:textarea>
        <v:button name="submit1" action="simple" value="OK"/>
      </v:form>
    </body>
  </html>
</v:page>
```

Example 14.31. Validation of text area input with separate error summaries place

The form contains two v:textarea controls with v:validator elements inside. When the OK button is pressed data are posted back to the same URI so the page is instantiated again. If any validator found a violation the message is shown to the user in the place specified by v:error-summary element depending of a match attribute.

```
<v:page name="error_summary__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:error-summary</title>
    </head>
    <body>
      <v:error-summary match="ta1"/>
      <v:form name="form1" type="simple" action="" method="POST">
        <v:textarea name="ta1" default="enter your first text here" value="--coalesce ({?'ta1'}, control.
          <v:validator test="length" min="0" max="50" message="The length of the first input should not e
        </v:textarea>
      <v:error-summary match="ta2"/>
        <v:textarea name="ta2" default="enter your second text here" value="--coalesce ({?'ta1'}, control
          <v:validator test="length" min="0" max="50" message="The length of the second input should not
        </v:textarea>
        <v:button name="submit1" action="simple" value="OK"/>
      </v:form>
    </body>
  </html>
</v:page>
```

expression

expression — An SQL statement that generates a rowset for v:data-source.

Synopsis

<**expression** /> (*language* (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

A container for SQL statement generating a rowset or table name (see data-source).

Attributes

language = SqlName . Denotes the type of language, currently only SQL expressions are supported, see 'expression-type' attribute of the data-source control.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

field

field — Name of input to be sent to and back between pup-up and parent window.

Synopsis

<**field** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
ref (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This element may occur under browse-button or select button, it enumerates the names of inputs to be sent between pop-up and parent window.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

ref = SqlName . When a field is used as child of and return button then this must contain valid reference to name of a input control (like text, select-list, data-list etc.) from current page. The referenced control's value will be used to set the value of control with name specified in attribute 'name' in the target page. The data will be set using automatically generated JavaScript function.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

form

form — Generic scriptable container for elements that may accept user's input.

Synopsis

<**form** /> (*name* (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
type (optional) ,
action (optional) ,
method (optional) ,
table (optional) ,
if-not-exists (optional) ,
concurrency (optional) ,
triggers (optional) ,
data-source (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This is a grouping element for controls that handle post data and validation of user's input. In case of type 'update', this is a single row update control for a database table. This retrieves the data from the row identified by the keys and shows the data in the column bound fields enclosed. If responding to a post for a submit inside this form, the form updates/inserts the data and shows the resulting state at the render pass.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the

name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

type. Type of form, can be 'simple' or 'update'. When this is 'simple' the vspx_form class will be instantiated, otherwise in case of 'update' vspx_update_form subclass will be used.

Table 14.6. Allowed values of the 'type' attribute

simple	Form with no special data binding.
update	Form that may be used in templates of type 'update' or 'add'.

action. A URL for processing. The data filled-in the form will be submitted to the 'action' page. Therefore this is a page where the content of that form will be processed. If it is empty, the target is a current page.

method. A method of transferring the form data, can be POST or GET. The same as 'method' of HTML forms.

The use of 'GET' is not recommended because the length of the URI may easily exceed internal limits of the browser or an intermediate proxy server.

table. If the value of 'type' attribute is 'update', the form acts as a single row update control for a database table; and the value of 'table' attribute specifies the name of that table. It retrieves the data from the row identified by the keys and shows the data in the column bound fields enclosed. If responding to a post for a submit inside this form, the form updates/inserts the data and shows the resulting state at the render pass. This attribute is required if 'type' is 'update' and prohibited otherwise.

if-not-exists. If the keys do not select any row, and the value of this attribute is 'insert', the update form will be filled in with defaults filled in and will do an insert into the table when the form is submitted. In this case of course the keys will have to be defaulted after the post or will have to be supplied in the post as fields. Any defaulting should take place in the v:on-post handler which is before the insert or update in the event of the post.

concurrency. If true and a previous value was shown in the form before the post being processed, this causes the system to check whether any of the data has been updated between getting it and the post at hand. This is a sort of optimistic concurrency control at the row level. If an update is detected, the updated_meanwhile message is set as the error message of the form and no update is made. The render pass may choose to process this message as it will, the default is to show it as any other error message for form level validation failure.

triggers. This is applicable for update form only, when this is OFF no PL triggers will be fired when inserting or updating.

data-source = SqlName . This is applicable to the update form and is An alternative of 'table'. When is specified the value is suppsed to be valid reference to existing data-source control. Further the given data-source will be used to bind/update the data.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_form

```
create type vspx_form under vspx_control
   as
     (
       uf_action varchar default '',
       uf_method varchar default 'post',
```

```
        --uf_inside_form int default 0,
        uf_validators any,
        uf_xmodel any default null,
        uf_xsubmit any default null,
        uf_xschema any default null
      )  temporary self as ref
    constructor method vspx_form (name varchar, parent vspx_control),
    method prologue_render (sid varchar, realm varchar, nonce varchar) returns any,
    method epilogue_render () returns any,
    overriding method vc_set_model () returns any
```

Examples

Example 14.32. Simple entry form

The OK button of the form submits data from the form back to the same page.

```
<v:page name="form__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:form</title>
    </head>
    <body>
      <v:form name="form1" type="simple" action="" method="POST">
        <v:label name="label1" value="--'Simple form'"/>
        <v:text name="txt1" default=""/>
        <v:text name="txt2" default=""/>
        <v:button name="submit1" action="simple" value="OK"/>
      </v:form>
    </body>
  </html>
</v:page>
```

Example 14.33. Simple entry form containing various controls

The OK button of the form submits data from the form back to the same page. The check-box is validated against ragio group:

```
<v:page name="form__1" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:form | v:validator</title>
    </head>
    <body>
      <v:form name="f1" type="simple" method="POST">
        <v:error-summary/><br/>
        <v:label name="l1" value="--'Simple form'"/><br/>
        <v:url name="u1" value="--'This page'" url="--self.f1.uf_action" /><br/>
        <v:text name="t1" value="--self.rb1.ufl_value"/><br/>
        <v:text name="t2" value="--'my'||'password'" type="password"/><br/>
        <v:text name="t3" value="--'something'||'hidden'" type="hidden"/>
        <v:textarea name="ta1" value="--'some text'" /><br/>
        <v:check-box name="cb1" value="check-box" /><br/>
        <v:radio-group name="rg1">
         <v:radio-button name="rb1" value="one" />
         <v:radio-button name="rb2" value="two" />
        </v:radio-group><br/>
        <v:button name="b1" action="simple" value="--'OK'"/><br/>
        <v:validator test="sql" message="only when radio is on position one check-box could be checked">
        if (self.rb2.ufl_selected and self.cb1.ufl_selected)
          {
            return 1;
          }
        </v:validator>
      </v:form>
    </body>
  </html>
</v:page>
```

VX-S-2

VX-S-3

hidden

hidden — A wrapper that prevents WYSIWYG editors from displaying its content.

Synopsis

<**hidden** /> (
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control does not affect the resulting HTML and Virtuoso/PL code. It is used by some WYSIWYG editors in order to temporarily hide details of the page fragment from the editor's drawing area.

Attributes

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

horizontal-template

horizontal-template

Synopsis

<**horizontal-template** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_horizontal_template

```
create type vspx_horizontal_template under vspx_control
as ( vc_stub any ) temporary self as ref
```

include

include — A place where the source code of other page should be inserted.

Synopsis

<include /> (
url (required) ,
active (optional) ,
initial-active (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

The VSPX compiler replaces this control with the content of another page. This will include the content from the specified url at this point of the page. The url is relative to the page. The inclusion will be done before compilation of VSPX into Virtuoso/PL, hence the include can contain either vspx or static HTML content. The only requirement is that the included file be well formed. Note also that if you are using vspx namespace in the include file, it must be declared as such. This element will not be instantiated. instead of instantiating it will be replaced with content of the specified document. The included page may or may not contain a 'page' element. If a 'page' element is found in the included file this will be skipped in the resulting page. Also names of controls in the included file MUST NOT conflict with names of controls in the top level page or other included content.

Attributes

url. URL of file to be included. If relative then the base is the page where the control resides. E.g. If '/home/pageA' includes 'subdir1/pageB' and the included page includes 'subdir2/pageC' then 'pageC' should reside in '/home/subdir1/subdir2', not in '/home/subdir2'.

active = CalculateableValue . A data bound value to enable or disable the link. The default is '1' meaning 'enable'.

initial-active = CalculateableValue . A data bound value to enable or disable the link. The default is '1' meaning 'enable'. Unlike 'active' attribute, this one is effective only when the page is displayed in the first time, not after user posts data back to the page.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Examples

Example 14.34. Include a common back-link into the end of page

If the file footer.xml is placed in the same directory where this sample page is located and contains the paragraph <P>Back to index</P> then the resulting page will have additional paragraph at the end.

```
<v:page name="include__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head><title>VSPX samples | v:include</title></head>
    <body>
      <p>The link after the horizontal ruler is included from footer.xml</p>
      <hr/>
      <v:include url="footer.xml"/> <!-- this will include the file described above -->

    </body>
  </html>
</v:page>
```

isql

isql — An interactive SQL control that allows the user to type an SQL statement and to see the result of its execution.

Synopsis

<**isql** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
isolation (optional) ,
timeout (optional) ,
maxrows (optional) ,
user (optional) ,
password (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of

this attribute will not be used when the resulting HTML is rendered.

isolation. Transaction isolation level to be used.

Table 14.7. Allowed values of the 'isolation' attribute

uncomitted	'uncomitted' transaction isolation level
committed	'committed' transaction isolation level
repeatable	'repeatable' transaction isolation level
serializable	'serializable' transaction isolation level

timeout = CalculateableValue . Query time-out in seconds (currently not supported)

maxrows = CalculateableValue . Maximum number of rows to be displayed.

user = CalculateableValue . SQL user account to perform the query, if not specified the SQL account used to run the VSPX page will be used.

password = CalculateableValue . When the 'user' attribute is supplied, this is the user's password.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_isql

A isql control

```
create type vspx_isql under vspx_form
as
 (
   -- parameters
   isql_custom_exec integer default 0,  -- do nothing to allow vspx code to perform actual exec (i.e. dat
   isql_explain integer default 0,  -- explain instead of execute
   isql_maxrows integer default 20,
   isql_chunked integer default 0,
   isql_current_stmt varchar default null,
   isql_current_state any default null,
   isql_current_meta any default null,
   isql_current_pos int default 0,
   isql_current_row int default 0,
   isql_rows_fetched int default 0,
   isql_user varchar default null,
   isql_password varchar default null,
   isql_isolation varchar default 'committed',
   isql_timeout integer default 60,
   isql_text varchar default '', -- sql text to execute
   --results
   --also used vc_error_message as vector(vector('sqlstate','sqlmessage'), ... ) for multiple statements
   isql_mtd any default null, --as vector(mtd, ... ) for multiple statements
   isql_res any default null,  --as vector(res, ... ) for multiple statements
   isql_stmts any default null -- array of statements to be executed on render as cursors
 )
   temporary self as ref
  constructor method vspx_isql (name varchar, parent vspx_control),
  method isql_exec () returns any
```

item

item — Item representing a selection inside a select list.

Synopsis

<item /> (*name* (required) ,
value (required) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Item representing a selection inside a select list.

Attributes

name = SqlCode . The visible value of the option, it will be shown in the option list.

value. The key value of the option, it will be assigned to the select control ufl_value is given option is seelcted.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

key

key — A key value of the vspx:form of type 'update'.

Synopsis

<**key** /> (*name* (optional) ,
column (required) ,
value (required) ,
default (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control defines a key value of the vspx:form of type 'update'. All the vspx:key children together should select one or zero rows from the table. Controls inside the form will process fields of this selected row.

Attributes

name = SqlName . Not used

column = SqlName . Name of the column in the table to be updated. This may be either the name of a primary key column or an other column, as long as the selection specified by all vspx:key children of the vspx:form is unambiguous.

value = CalculateableValue . The value of the key field referred to by the 'column' attribute.

default = CalculateableValue . The default value to be used when the 'value' expression returns NULL.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

label

label — Generic scriptable text.

Synopsis

<label /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
column (optional) ,
null-value (optional) ,
value (optional) ,
element-value (optional) ,
element-place (optional) ,
element-path (optional) ,
element-params (optional) ,
element-update-path (optional) ,
element-update-params (optional) ,
fmt-function (optional) ,
cvt-function (optional) ,
format (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This is for displaying a value as plain text. The underlying class is derived from VSPX_FIELD so the value to be displayed is accessible as a value of any VSPX field.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if

'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

format. A sprintf format string for printing the value

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_label

```
create type vspx_label under vspx_field
as
(
  vl_format varchar default '%s'
) temporary self as ref
constructor method vspx_label (name varchar, parent vspx_control),
overriding method vc_render () returns any
```

Examples

Example 14.35. Simple dynamic text

This page demonstrates output of data values of various types.

```
<v:page name="label__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head><title>VSPX samples | v:label</title></head>
    <body>
        Float: <v:label name="flo" value="--3.14" format="%d" /><br/>
        Integer: <v:label name="intgr" value="--2+2" format="%d" /><br/>
        String: <v:label name="strg" value="--'The quick brown fox has stopped his jumping over the lazy
    </body>
  </html>
</v:page>
```

leaf-template

leaf-template

Synopsis

```
<leaf-template /> (   name (required) ,
                      annotation (optional) ,
                      initial-enable (optional) ,
                      enabled (optional) ,
                      instantiate (optional) ,
                      control-udt (optional) ,
                      xsd-stub-xhtml (optional) ,
                      width (optional) ,
                      height (optional) ,
                      debug-srcfile (optional) ,
                      debug-srcline (optional) ,
                      debug-log (optional) ) ;
```

Description

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_leaf_template

```
create type vspx_leaf_template under vspx_control
as ( vc_stub any ) temporary self as ref
```

local-variable

local-variable — Local variable - an invisible control to store a temporary value.

Synopsis

<**local-variable** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
value (optional) ,
element-value (optional) ,
element-place (optional) ,
element-path (optional) ,
element-params (optional) ,
element-update-path (optional) ,
element-update-params (optional) ,
fmt-function (optional) ,
cvt-function (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This tag declares a control that can store a temporary value that can be accessed from other controls. Usually it is an intermediate value that is used by a group of controls of the same form. E.g. if controls of a form display various data stored in a complex object then it may be convenient to obtain this object once and place it into value of a local-variable control that is the first child control of a form. The rest of child controls may access the value from the first child to calculate their values.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its

attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of

ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

login

login — Authentication parameters of a page.

Synopsis

<login /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
realm (required) ,
mode (required) ,
user-password (optional) ,
user-password-check (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

The login control controls authentication for its page. Depending on options this may or may not be visible. This works together with a login-form and logout-button controls. The storage of passwords and user names is left to the application, which can specify functions called by these widgets. The server keeps login information in the following table:

```
create table VSPX_SESSION (VS_REALM varchar, VS_SID varchar, VS_UID varchar, VS_STATE long varchar,
  primary key (VS_REALM, VS_SID));
```

This table is shared between all vspx applications, each with their login differentiated by realm. The state is an array of name value pairs which will be accessed through connection_get and connection_set inside the page code. There are three methods of keeping session state:URL-poisoning, digest authentication and Cookies.The URL-poisoning scheme presents a login dialog form and sets a session ID as hidden form element. Digest authentication uses an opaque value as session id and is available only for browsers that support standard HTTP 1.1 digest authentication. The Cookie is an analogue of URL poisoning, but in that case session ID is kept as a Cookie, thus cookies must be enabled on the browser. The login control is mandatory when using a persistent page variables (see persist="session" attribute of 'variable' control). This is because HTTP protocol is state-less; therefore value of such variables have to be stored in a table and restored on next hit with same session ID (and realm). Hence as login control maintains a session state (via some mechanism, see notes above), this capability is used to maintain persistent page variables. Note also that persistent page variables can be used between different pages, in that case all of those pages need to have login control (in most cases it is invisible).

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

realm. This is the authentication realm name.

mode. This specifies the preferred mode of keeping session and login information. In the case of url and cookie the name and password will have to be supplied in a form submit. The vspx:login-form control provides a convenient way of doing this. If passwords are transmitted in a form submit, it is best for security to have the login page accessed via SSL only. Many values may be separated by spaces. This is the order of preference. The system will use the first available depending on the user agent.

Table 14.8. Allowed values of the 'mode' attribute

digest	HTTP digest authentication is used and the session id will travel as the opaque data in the digest headers.
url	The url mode means that URL poisoning is used and that the session id passes with the links, posts etc. Some automation is offered for this by the vspx:url and vspx:form and derived controls.
cookie	The session id is set in a cookie on browser.

user-password. The name of a SQL function which will retrieve the password given a user name. If digest authentication is to be possible, this function must be specified. Example:

```
create procedure
sql_user_password (in name varchar)
{
  declare pass varchar;
  pass := NULL;
  whenever not found goto none;
  select pwd_magic_calc (U_NAME, U_PASSWORD, 1) into pass
          from SYS_USERS where U_NAME = name and U_SQL_ENABLE = 1 and U_IS_ROLE = 0;
none:
  return pass;
}
;
```

user-password-check. This is a function which takes the user name and password (unencrypted) and returns true if these match, false otherwise.

```
create procedure
sql_user_password_check (in name varchar, in pass varchar)
{
  if (exists (select 1 from SYS_USERS where U_NAME = name and U_SQL_ENABLE = 1 and U_IS_ROLE = 0 and
        pwd_magic_calc (U_NAME, U_PASSWORD, 1) = pass))
    return 1;
  return 0;
}
```

```
;
```

If the application will keep a session state which will automatically be extracted from the application's user repository upon login, then either of these functions may set this using connection_set. This will persist in the session if the login is successful and will be discarded otherwise. An example of such information is a user privilege class, real name, email or such. These functions may be called one or more times during the session, but no more than one call at the start is guaranteed.

Example:

Note: when the mode is digest the login control will only call user_password and in other modes it will only call user_password_check.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_login

```
create type vspx_login under vspx_form
as (
    vl_realm varchar,
    vl_mode varchar,
    vl_pwd_get varchar,
    vl_usr_check varchar,
    vl_authenticated int default 0,
    vl_user varchar,
    vl_sid varchar,
    vl_no_login_redirect varchar,
    vl_logout_in_progress int default 0
   )
 temporary self as ref
overriding method vc_view_state (stream any, n int) returns any,
overriding method vc_set_view_state (e vspx_event) returns any,
constructor method vspx_login (name varchar, parent vspx_control)
```

Examples

Example 14.36. Simple login dialog

This example will show simltaniously 'not-autneticated' message and a simple post counter.

```
<v:page name="login__0" xmlns:v="http://http://example.com/vspx/">
<html>
  <body>
      <v:variable name="ctr" type="int" persist="session" default="0"/>
      <v:login name="lc1" realm="vspx" mode="url" user-password-check="sql_user_password_check">
        <v:template type="if-no-login">You are not logged in</v:template>
        <v:login-form name="f1" required="1" title="Login" user-title="User Name" password-title="Passwor
        <v:template type="if-login">
    Posted #: <v:label name="l1" value="--self.ctr" format="%d"/>
          <v:button name="b1" action="simple" value="Reload">
            <v:on-post>
                self.ctr := self.ctr + 1;
                self.l1.vc_data_bind (e);
                </v:on-post>
          </v:button>
          <v:button name="b2" action="logout" value="Logout"/>
        </v:template>
      </v:login>
  </body>
</html>
</v:page>
```

VX-S-6

login-form

login-form — A form to be shown if the user is not logged in.

Synopsis

<login-form /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
required (required) ,
title (optional) ,
user-title (optional) ,
password-title (optional) ,
submit-title (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

login-form is the control for getting login information. This may only appear inside a login. Its function will depend on the type of login being attempted. If the type is digest, this is a button which, when submitted, will send the digest challenge.

If the url or cookie session mode is chosen, this will be a form of 2 fields with user name and password and a submit button.

if the standard form is not suitable, this can be an arbitrary form. This must post buttons values named "username" and "password" and a submit button named "login". No children need be specified if the default form is OK.

If the redirect attribute of template[@type=if-no-login] is not specified, the contents of this child are instantiated and shown in the place of the login control. This can be arbitrary content.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX

compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

required. If digest is the mode, then this means that the login is mandatory and that instead of displaying the login button which will send the challenge if pressed, the challenge will be sent automatically.

title. Title of login button if digest is attempted.

user-title. Title of user name field

password-title. Title of password field

submit-title. Title of submit button

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_login_form

```
create type vspx_login_form under vspx_form
as
  (
   vlf_title varchar,
   vlf_user_title varchar,
   vlf_password_title varchar,
   vlf_submit_title varchar,
   vlf_login vspx_login
  ) temporary self as ref
constructor method vspx_login_form (name varchar,  parent vspx_control),
constructor method vspx_login_form (name varchar, title varchar, user_title varchar, password_title varch
overriding method vc_render () returns any
```

Examples

Example 14.37. A simple default login-form

This example will render just a login form:

```
<v:page name="login_form__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head><title>VSPX samples | v:login-form</title></head>
    <body>
      <v:login name="login_0" mode="url" user-password-check="sql_user_password_check" realm="vspx">
        <v:login-form name="login_form_0"
          required="1"
          title="Login"
          user-title="User Name"
          password-title="Password"
          submit-title="Login"/>
        </v:login>
    </body>
  </html>
```

```
</v:page>
```

method

method — Page method - a user defined member of page class.

Synopsis

<**method** /> (*name* (required) ,
returns (optional) ,
arglist (optional)) ;

Description

This creates a custom method of the page class.

Attributes

name = SqlName . The name of method to be created

returns = SqlName . Optional return datatype type

arglist. comma-separated list of arguments. For example : "in arg1 varchar, out arg1 integer ..."

node

node — A place holder for rendering a tree node.

Synopsis

<node /> (
void (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control indicates the place of a subtree inside a node template.

Attributes

void. Not used.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

node-template

node-template

Synopsis

<node-template /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_node_template

```
create type vspx_node_template under vspx_control
as ( vc_stub any ) temporary self as ref
```

on-init

on-init — Container for code that should be executed at the end of control instantiation.

Synopsis

```
<on-init >(EventHandler)</on-init >(    );
```

Description

The code contained in this element is executed at the end of the control's constructor. This is expected to have additional initialization checking etc.

on-init-container

on-init-container — This is identical to v:on-init.

Synopsis

```
<on-init-container >(EventHandler)</on-init-container >(    );
```

Description

on-post

on-post — Container for code that should be executed when the element gets a post.

Synopsis

```
<on-post >(EventHandler)</on-post >(   );
```

Description

The code contained in this element is executed when the element gets a post. For fields and forms, this is a context for an a SQL compound statement that will be executed. The statement should end with a return 1 or 0. The implicit return is 0. A return of 1 means that the post is fully handled here and not to be passed on to the parent chain. A 0 means that the post was not handled and the next control up the chain will try.

The context has a self which is the page, a vspx_control which is the control which defines this handler, and a origin_control, which is the control that first got the post event. This will be a data field or button. The vspx_event with the post's data will be in the variable event.

The interpretation of the return value is the same for other event handlers. SQL conditions signalled will go to the page, these condition handlers are invoked in no special context, hence the declare handler for SQL construct should not be used to pass control between handlers, but only within handlers.

on-post-container

on-post-container — This is identical to v:on-post.

Synopsis

```
<on-post-container >(EventHandler)</on-post-container >(    );
```

Description

page

page — Container of VSPX code.

Synopsis

<**page** /> (
name (required) ,
decor (optional) ,
style (optional) ,
on-error-redirect (optional) ,
on-deadlock-retry (optional) ,
doctype (optional) ,
doctype-system (optional) ,
page-subclass (optional) ,
file-name (optional) ,
no-script-function (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

The container for the rest of the vspx code. The page or a subclass of it will be the outermost VSPX element on any VSPX page. Each .vspx file defines explicitly one custom page class derived from vspx_page. This element can enclose all HTML elements or can be incorporated in it's children on place apropriate for rendering the VSPX controls, but one VSPX page must contain only one vspx:page element. and noe VSPX-specific element may appear outside the vspx:page. It can be placed in other HTML stuff or around it, doesnt' matter, but VSP & VSPX code must be inside it (the same applies to customized HTML attributes, i.e. containing <?V & <?U shortcuts). Note that when using 'include' or 'decoration' features the top level page element will be : in case of include - 'this' page, in case of 'decoration' - the decoration page. Also page variables, controls will be combined in all cases of inclusion or macro-expansion, so their names must not be duplicated; this means that names of variables introduced by macro expansion or inclusion must not conflict with cnames of variables or controls in the top level page or any included or macro content.

Attributes

name = SqlName . The name of subclass of vspx_page to be generated. The name of class will be prefixed with 'page_' plus that name.

decor. This attribute specifies a 'decoration' page URL. The decoration page is a VSPX page that is wrapped around the including page. The content of the including page is then put in the place indicated by a placeholder element in the decor page. This is useful for defining enclosing tables, headers, footers and other repeating content.

style. This designates an external XSL-T style sheet to be apply over the page, before page compilation. This is useful as a 'macro' feature. The XSLT sheet may define rules for macroexpanding things in the page body.

on-error-redirect. This specifies where to redirect the HTTP client in the event of an an unhandled error. This will pass a __SQL_STATE, __SQL_MESSAGE and __PAGE as parameters to the error page.

on-deadlock-retry. This specifies how many times to retry page execution upon deadlock. When the number of retries is reached, the behaviour will be as for other SQL errors.

doctype. This is to specify the resulting document type declaration (DTD) public URI.

doctype-system. This is to specify the resulting document type declaration (DTD) system URI.

page-subclass = SqlName . The name of page subclass to be instantiated for processing. The subclass with this name MUST already be defined. The subclass definition can be kept in a code-behind file (see code-file element).

file-name. The name of page to be generated. Used by wizards to designate where generated page will be stored. This attribute do not affect VSPX processing.

no-script-function. A function to enable or disable automatic NOSCRIPT element generation.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_page

VSPX Page Class , from it must be derived all VSPX pages, no subcalsses for others

```
create type vspx_page under vspx_control
as (
    vc_view_state any,
    vc_is_postback int default 0,
    vc_persisted_vars any,
    vc_event vspx_event,
    vc_is_valid int default 1,          -- set to 0 when first validator fails
    vc_authenticated int default 0,     -- is true if login control in the page suceeded
    vc_current_id int default 0,
    vc_browser_caps any default 0,
    vc_authentication_mode int default 1, -- authentication mode 0 - cookie, 1 - url, 2 - digest
    vc_debug_log_acc any default null   -- The accumulator in xte_nodebld_... style for keeping debugging
    )  temporary self as ref
  method vc_state_deserialize (stream any, n int) returns any,
  method vc_get_debug_log (title varchar) returns any
```

Examples

Example 14.38. Sample VSPX page

```
<v:page name="page__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head><title>VSPX samples | v:page</title></head>
    <body>
      <p>This VSPX page does nothing.<br/>
It does not even print traditional 'Hello world' phrase.</p>
    </body>
  </html>
</v:page>
```

VX-S-1

VX-S-8

param

param — Named parameter for the cursor.

Synopsis

<**param** /> (
name (required) ,
value (required) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Named parameter for execution of the cursor select statement. This must be the name of a parameter for SQL statement specified, but without leading colon.

Attributes

name = SqlName . Name of the parameter.

value = CalculateableValue . Data bound value of the parameter.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

placeholder

placeholder — Placeholder for original page in the decoration page.

Synopsis

<**placeholder** /> (
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This marks the place in the decoration page where the content of the original page should be placed.

Attributes

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

radio-button

radio-button — Scriptable radio button.

Synopsis

<**radio-button** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
column (optional) ,
null-value (optional) ,
error-glyph (optional) ,
auto-submit (optional) ,
group-name (optional) ,
value (optional) ,
element-value (optional) ,
element-place (optional) ,
element-path (optional) ,
element-params (optional) ,
element-update-path (optional) ,
element-update-params (optional) ,
fmt-function (optional) ,
cvt-function (optional) ,
initial-checked (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

is a scriptable version of HTML radio button.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated

before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

error-glyph. The character to be displayed near the resulting HTML input element if the test of v:validator of the element detects an error in the current value of the element.

auto-submit. Flag to auto submit the parent form if value of the control is changed.

group-name. When several check boxes are to be grouped, this is the name of the group. Upon post the name of the group will be submitted instead of the than name of the control. This also will restrict in the group to have more than one button on

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

initial-checked. This flag specifies whther this control is initially checked.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_radio_button

```
create type vspx_radio_button under vspx_field
temporary self as ref
constructor method vspx_radio_button (name varchar, parent vspx_control),
overriding method vc_view_state (stream any, n int) returns any,
overriding method vc_set_view_state (e vspx_event) returns any,
overriding method vc_render () returns any,
overriding method vc_xrender () returns any,
overriding method vc_set_model () returns any
```

Examples

Example 14.39. Groups of radio buttons.

The form contains two groups of radio buttons, three button in each group.

```
<v:page name="radio_button__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:radio-button</title>
    </head>
    <body>
      <v:form name="form1" type="simple" action="" method="GET">
        <input type="text" name="qq"/>
        <table>
          <tr>
            <td>
              <v:radio-button name="radio1" group-name="radio_group_A" value="--'A-one'" initial-checked=
```

```
            <v:radio-button name="radio2" group-name="radio_group_A" value="--'A-two'"/>
            <v:radio-button name="radio3" group-name="radio_group_A" value="--'A-three'"/>
          </td>
        </tr>
        <tr>
          <td>
            <v:radio-button name="radio4" group-name="radio_group_B" value="--'B-one'" initial-checked=
            <v:radio-button name="radio5" group-name="radio_group_B" value="--'B-two'"/>
            <v:radio-button name="radio6" group-name="radio_group_B" value="--'B-three'"/>
          </td>
        </tr>
      </table>
      <v:button name="submit1" action="simple" style="image" xhtml:alt="A test button" value="--'plus.g
    </v:form>
  </body>
 </html>
</v:page>
```

See Also: Reference Material in the Tutorial:
VX-S-2

radio-group

radio-group — A group of radio-buttons.

Synopsis

<**radio-group** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
error-glyph (optional) ,
auto-submit (optional) ,
column (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control is used to group containing radio-buttons in a group. This ensures that only one button is selected at a time. Note: This control is not mandatory for making such group of buttons, another option is to use 'group-name' attribute of the radio-button control.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

error-glyph. The character to be displayed near the resulting HTML input element if the test of v:validator of the element detects an error in the current value of the element.

auto-submit. Flag to auto submit the parent form if value of the control is changed.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_radio_group

```
create type vspx_radio_group under vspx_field
temporary self as ref
constructor method vspx_radio_group (name varchar, parent vspx_control),
method vc_choose_selected () returns any,
overriding method vc_xrender () returns any,
overriding method vc_set_model () returns any
```

Examples

Example 14.40. Groups of radio buttons.

The form contains a groups of radio buttons, grouped with radio-group control.

```
<v:page name="radio_group_demo" xmlns:v="http://http://example.com/vspx/">
<html>
<body>
  <v:form name="sf" type="simple" method="POST">
     <v:radio-group name="radio00">
       <v:radio-button name="radiob01" value="--'one'" />
       <v:radio-button name="radiob02" value="--'two'" />
     </v:radio-group>
  </v:form>
</body>
</html>
</v:page>
```

See Also: Reference Material in the Tutorial:

VX-S-2

VX-S-3

script

script — A (redundant) wrapper for SQL code, can be omitted.

Synopsis

<**script** /> (*language* (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control can appear only inside event handling controls and it always contain SQL code to be executed when the event occurs. There is no difference for VSPX compiler whether SQL code is enclosed in 'script' control or not. Some WYSIWYG tools can display the enclosed SQL code to the application developer according to custom attributes of this control but it does not affect the generated Virtuoso/PL code of the page.

Attributes

language = SqlName . Denotes the type of language, currently only Virtuoso/PL expressions are supported.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

select-list

select-list — Fixed initialized select list.

Synopsis

<**select-list** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
column (optional) ,
null-value (optional) ,
error-glyph (optional) ,
auto-submit (optional) ,
multiple (optional) ,
value (optional) ,
element-value (optional) ,
element-place (optional) ,
element-path (optional) ,
element-params (optional) ,
element-update-path (optional) ,
element-update-params (optional) ,
fmt-function (optional) ,
cvt-function (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This is a scriptable version of HTML select control. It shows a static list of items (see item element). Databind and on-post scripts are allowed.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated

before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

error-glyph. The character to be displayed near the resulting HTML input element if the test of v:validator of the element detects an error in the current value of the element.

auto-submit. Flag to auto submit the parent form if value of the control is changed.

multiple. Used to designate a multiple selection list box. In this case the control's value will be an array of key data of selected items.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_select_list

```
create type vspx_select_list under vspx_field
as (
     vsl_items any,
     vsl_item_values any,
     vsl_selected_inx any default null,
     vsl_change_script int default 0,
     vsl_list_document any default null,
     vsl_list_match varchar default null,
     vsl_list_key_path varchar default null,
     vsl_list_value_path varchar default null,
     vsl_multiple int default 0
   )
  temporary self as ref
 overriding method vc_render () returns any,
 overriding method vc_view_state (stream any, n int) returns any,
 overriding method vc_set_view_state (e vspx_event) returns any,
 overriding method vc_set_model () returns any,
 overriding method vc_xrender () returns any,
 method vs_set_selected () returns any,
constructor method vspx_select_list (name varchar, parent vspx_control)
```

Examples

Example 14.41. A simple static select list

The form of the sample page contains a list of three items.

```
<v:page name="select_list__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
```

```
      <title>VSPX samples | v:select-list</title>
    </head>
    <body>
      <v:form name="form1" type="simple" action="" method="POST">
        <v:select-list name="sel_list">
          <v:item name="*default*" value="0"/>
          <v:item name="FIRST" value="1"/>
          <v:item name="SECOND" value="2"/>
        </v:select-list>
        <v:button name="submit1" action="simple" value="OK"/>
      </v:form>
    </body>
  </html>
</v:page>
```

VX-S-2

style

style — A markup tag for use by 'macro stylesheets'.

Synopsis

<**style** /> (*name* (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control marks the enclosed content for special processing in the 'macro stylesheet' whose name is specified by 'style' attribute of v:page element.

Attributes

name. Optional name of the control which could be used in the macro expansion stylesheet assigned.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

tab

tab — Selects one of its children to be active at any one time.

Synopsis

<tab /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
initial-active (optional) ,
style (optional) ,
active (optional) ,
is-input (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

A container that contains some number of pages and displays them one by one. This can be used for multi-page forms or Windows style tabbed decks or making multi-part forms, alternative visualizations of the same data etc.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

initial-active = SqlName . This is the name of the child template which is active at the time and which thus will be rendered. Whether inactive templates are instantiated and keep state is controlled by is-input. The active attribute initializes the tb_active member of the vspx_tab instance. This is preserved in the view state. Data bindable.

style. This determines what HTML control is used to select which child is shown. If unspecified, there will be no such control and the program logic is responsible for flipping the pages. Otherwise "list" means there is a HTML select control showing the titles of the tabs. "radio" means the titles of the tabs are shown as a radio group. If there is a tab selector widget, it is always above the tabs.

active = CalculateableValue . A data bound value to enable or disable the tab switch. The default is '1' meaning 'enable'.

is-input. If true, all the children are considered to be collectively a multipart form and each will be instantiated when the page is made and will get to retain a view state. Although only one page of the form is shown at a time, the state of all is kept. Not data bindable. The default is '1' meaning 'template contains input'.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_tab

Tab Deck

```
create type vspx_tab under vspx_form
as
   (
     tb_active vspx_template,
     tb_is_input int default 0,
     tb_style varchar
   )
    temporary self as ref
   constructor method vspx_tab (name varchar, parent vspx_control),
   --overriding method vc_render () returns any,
   overriding method vc_set_view_state (e vspx_event) returns any,
   overriding method vc_view_state (stream any, n int) returns any
```

Examples

Example 14.42. Switching of page content

The sample page contains three templates; only one of three is shown and user can switch them to change the visible content of the page.

```
<v:page name="tab__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head><title>VSPX samples | v:tab</title></head>
    <body>
      <v:tab name="tab" initial-active="template1" style="list" is-input="0">
        <v:template name="template1" type="simple">This is a first template</v:template>
        <v:template name="template2" type="simple">This is a second template</v:template>
        <v:template name="template3" type="simple">This is a third template</v:template>
      </v:tab>
    </body>
  </html>
</v:page>
```

VX-S-5

template

template — Container for a group of controls and/or HTML code.

Synopsis

```
<template /> (   name (required) ,
                 annotation (optional) ,
                 initial-enable (optional) ,
                 enabled (optional) ,
                 instantiate (optional) ,
                 control-udt (optional) ,
                 xsd-stub-xhtml (optional) ,
                 width (optional) ,
                 height (optional) ,
                 type (optional) ,
                 redirect (optional) ,
                 condition (optional) ,
                 name-to-remove (optional) ,
                 set-to-remove (optional) ,
                 title (optional) ,
                 debug-srcfile (optional) ,
                 debug-srcline (optional) ,
                 debug-log (optional) ) ;
```

Description

The container for any optional, repeatable or otherwise grouped controls or code. The type modifier is used to specify special kind of templates (i.e. repeatable content or tree node representation)

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

type. The behaviour of the template.

Table 14.9. Allowed values of the 'type' attribute

simple	The template contains an arbitrary number of controls and HTML tags and groups them together to control their processing, e.g. to enable or disable them altogether depending on some condition.
repeat	A repeating row of v:data-set. The template of this type will be repeated for each row in the window of the data-set. It will be instantiated, data bound, rendered. If the template contains forms and submits, they get the post method called as one would expect. On data binding, the parent of the template has its dg_current_row data member set to an array representing the selected row from left to right.
row	A repeating row of v:data-grid. The template of this type will be repeated for each row in the window of the v:data-grid. It will be instantiated, data bound, rendered. If the template contains forms and submits, they get the post method called as one would expect. On data binding, the parent of the template has its dg_current_row data member set to an array representing the selected row from left to right. The controls under this template (such as text, label, button etc.) can access data in current row in order as columns are given by referencing te_rowset member of row template.
frame	A non-repeating static content of v:data-grid. Content of this template represents view in page when rows are selected, position of scroll buttons, rowset and form for adding a record.
if-exists	Template that is enabled only if the resultset is not empty in v:data-set.
if-not-exists	Template that is enabled only if the resultset is empty in v:data-set.
add	Template that is enabled when user adds new record in the resultset in v:data-set (if the resultset is not read-only). Similarly to templates of type 'edit', the 'add' template contains a vspx:form of type 'update' that is used to allow adding of rows in table as specified. Usually this form is a vspx_form + vspx_text constrained to columns and table selected in SQL expression of the parent vspx:data-set control with value of key attributes set to null. Please remember to set the 'if-not-exists' attribute of the form to 'insert'.
browse	This type is meaningful only for templates right inside templates of type 'repeat'. When the template of type 'repeat' is used multiple times to display every row of a data-set, the template of type 'browse' expands only for those rows that are not currently editable.
edit	Template that is enabled when user edits an existing record in the resultset in v:data-set (if the resultset isnot read-only and if the 'edit' attribute of v:data-set is set to 'true'). The template of this type usually contains a vspx:form of type 'update'; the 'table' attribute of the form is the name of the table from 'sql' attribute of the v:data-set where the 'edit' template is located; controls of the form are usually constrained to columns of the SQL expression of that 'sql' attribute.
if-login	Template that is enabled when user is logged in (e.g. for use in v:login. If the login is valid, the contents of this child will be instantiated. This can be for example a button with 'action' attribute set to 'logout', a welcome message or such. When using the vspx:login system, the user name is is obtained by connection_get ('vspx_user').
if-not-login	Template that is enabled when user is not yet logged in or is already logged out (e.g. for use in v:login. The template specifies what to do if there are no credentials with the page. If the 'redirect' attribute is given, then the entire page containing this is not processed at all but instead the page specified in the url is processed instead, with the context being that of the invocation of this page. The redirect page can thus ask for the login and having checked it return to this page, since it knows the url for this. In this way it is possible to bookmark places of which the uri's may expire, and accessing an expired place will just prompt for the login before going to the page. If the redirect is not specified, the content of the template is instantiated and shown. The content can be arbitrary, e.g. the vspx:login-form control can appear here, providing a standard login form that prompts for a user name and password and has a submit button.
tree-node	Template for internal nodes of the tree in v:tree (i.e. for nodes with children).
tree-leaf	Template for terminal nodes of the tree in v:tree (i.e. for nodes without children).
input	Template for input the SQL statement to execute it interactively in v:isql element.
result	Template to show if v:isql returns result without an error.
error	Template to be shown by v:isql if the user entered the SQL query and the execution of this query caused an error.

redirect. The URL to which the user agent is redirected if not authenticated, applicable only when type is 'if-no-login'.

condition = SqlCode . This is a SQL expression to be tested for rendering the template

name-to-remove. This works together with set-to-remove, see next.

set-to-remove. This combined with name-to-remove gives posibility to remove a HTML elements from output.

Table 14.10. Allowed values of the 'set-to-remove' attribute

none	The rendered output of the enclosing template will not be affected by the 'name-to-remove' attribute of the template.
top	The rendered output of the enclosing template should not contain the first opening tag whose name is equal to the value of 'name-to-remove' attribute of the template.
bottom	The rendered output of the enclosing template should not contain the last closing tag whose name is equal to the value of 'name-to-remove' attribute of the template.
both	The rendered output of the enclosing template should not contain the both the first opening tag and the last closing tag whose name is equal to the value of 'name-to-remove' attribute of the template.

title. When used inside tab control, this is used to show as label of the selector

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_template

```
create type vspx_template under vspx_control
  temporary self as ref
 constructor method vspx_template (name varchar, parent vspx_control)
```

text

text — Scriptable, data-bindable input control.

Synopsis

```
<text /> (  name (required) ,
            annotation (optional) ,
            initial-enable (optional) ,
            enabled (optional) ,
            instantiate (optional) ,
            control-udt (optional) ,
            xsd-stub-xhtml (optional) ,
            width (optional) ,
            height (optional) ,

            element-params (optional) ,
            element-update-path (optional) ,
            element-update-params (optional) ,
            fmt-function (optional) ,
            cvt-function (optional) ,
            default-value (optional) ,
            default_value (optional) ,
            format (optional) ,
            debug-srcfile (optional) ,
            debug-srcline (optional) ,
            debug-log (optional) ) ;
```

Description

Text input, with scripts and validation options but no implied database binding. String input of the HTML form.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

error-glyph. The character to be displayed near the resulting HTML input element if the test of v:validator of the element detects an error in the current value of the element.

auto-submit. Flag to auto submit the parent form if value of the control is changed.

type.

Table 14.11. Allowed values of the 'type' attribute

plain	The value is displayed in a usual way and user can edit it. This is the default value.
password	The value is not shown on the screen to prevent occasional reading, only astericks are shown in the input field.
hidden	The text is passed to the target page without displaying it to the user.

default = CalculateableValue . The default value of input field.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename'

then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

default-value = CalculateableValue . This is an expression for setting the default value of the text.

default_value = CalculateableValue . This is deprecated alias for 'default-value' attribute (note the difference between minus sign and underscore).

format =

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_text

```
create type vspx_text under vspx_field
as
 (
   tf_default varchar default '',
   tf_style any default 0 -- 0 is text, 1 is password, 2 is hidden
 )
```

```
 temporary self as ref
  overriding method vc_render () returns any,
  overriding method vc_set_view_state (e vspx_event) returns any,
  overriding method vc_view_state (stream any, n int) returns any,
  overriding method vc_set_model () returns any,
  overriding method vc_xrender () returns any,
  constructor method vspx_text (name varchar, parent vspx_control)
```

Examples

Example 14.43. Simple text input

The form contains text input control with 'Hello' string inside. User can edit the string and submit the changed value:

```
<v:page name="text__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:text</title>
    </head>
    <body>
      <v:form name="form1" type="simple" action="" method="POST">
        <v:text name="txt01" default="Hello"/>
        <v:button name="submit1" action="simple" value="OK"/>
      </v:form>
    </body>
  </html>
</v:page>
```

textarea

textarea — Scriptable text-area input.

Synopsis

<**textarea** /> (

debug-log (optional)) ;

Description

Scriptable, databindable HTML text area.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

error-glyph. The character to be displayed near the resulting HTML input element if the test of v:validator of the element detects an error in the current value of the element.

auto-submit. Flag to auto submit the parent form if value of the control is changed.

type.

Table 14.12. Allowed values of the 'type' attribute

plain	The value is displayed in a usual way and user can edit it. This is the default value.
password	The value is not shown on the screen to prevent occasional reading, only astericks are shown in the input field.
hidden	The text is passed to the target page without displaying it to the user.

default_value = CalculateableValue . The default value of the field. Can be accessed via control.ufl_value n data bind stage.

default = CalculateableValue . Deprecated alias of 'default_value'.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either

the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_textarea

```
create type vspx_textarea under vspx_text  temporary self as ref
  constructor method vspx_textarea (name varchar, parent vspx_control),
  overriding method vc_xrender () returns any,
  overriding method vc_render () returns any
```

tree

tree — A container for displaying a tree of nested nodes.

Synopsis

```
<tree /> (  name (required) ,
            annotation (optional) ,
            initial-enable (optional) ,
            enabled (optional) ,
            instantiate (optional) ,
            control-udt (optional) ,
            xsd-stub-xhtml (optional) ,
            width (optional) ,
            height (optional) ,
            show-root (optional) ,
            multi-branch (required) ,
            orientation (required) ,
            root (required) ,
            child-function (required) ,
            start-path (required) ,
            open-at (optional) ,
            debug-srcfile (optional) ,
            debug-srcline (optional) ,
            debug-log (optional) ) ;
```

Description

This can be used for hierarchical tables of contents, directory browsing, hierarchical menus and such. The tree can have either one or more branches open at any time, up to the leaves. The tree has a root, which may or may not be visible. The contents of the tree can either be fixed, in which case these are an XML tree, or dynamic, in which case these are generated level by level by SQL functions attached to the tree. The tree can have various external appearences. The tree is represented at run time by a vspx_tree instance. Nodes of the tree are represented by vspx_tree_node objects, which are childs of the vspx_tree. The nodes hold an identifier (vc_instance_name) of the corresponding tree branch, which is used to retrieve children of the node. These also hold a flag (tn_open member) indicating if the node is open or not.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its

attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

show-root. This attribute is obsolete and has no effect.

multi-branch. This determines whether more than one branches can be open at one time. The values are 0 and 1 (true and false). The default is 0 (false).

orientation. This can be 'horizontal' or 'vertical', the default is 'vertical'. The tree can have different styles. The default is a vertical arrangement with open levels indented, the children under the parent node. Each node template is a single line. The horizontal style shows each level on a separate line. In this case it is not allowed multiple open branches. The children of the root will be shown on one line. When one is opened, its children will fill the next line.

root = SqlName . This is a SQL expression which produces the root object. This can be of any data type, a file system path is an example.

```
create procedure root_node (in path varchar)
{
  declare i, l int;
  declare ret, arr any;
  arr :=
    vector_concat (sys_dirlist (path, 0), sys_dirlist (path, 1));

  return arr;
};
```

child-function = SqlName . Given the result of the root expression, this must generate an array of similar elements corresponing to the children of the node in question. This same function should be applicable to each element of the array it returns. If the array is empty then the node in question is a leaf.

```
-- Example of this function

create procedure child_node (in node_name varchar, in node varchar)
{
  declare i, l int;
  declare ret, arr any;
  declare exit handler for sqlstate '*'
    {
      return vector ();
    };
  if (isstring (file_stat (node_name, 3)))
    return vector ();

  arr :=
    vector_concat (sys_dirlist (node_name, 0), sys_dirlist (node_name, 1));

  return arr;
}
;
```

start-path = CalculateableValue . This is an expression which will be evaluated and passed to the 'root' function as argument.

open-at = CalculateableValue . This is an expression which will be used as XPath expression to designate which branches of the tree are open and which are not initially.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_tree

```
create type vspx_tree under vspx_control
as
  (
    vt_current_node int default -1,
    vt_node any default null,
    vt_open_at varchar default null,
    vt_xpath_id varchar default null
  )
temporary self as ref
overriding method vc_view_state (stream any, n int) returns any,
method vc_get_state () returns any,
method vc_open_at (path varchar) returns any,
constructor method vspx_tree (name varchar, parent vspx_control)
```

Examples

Example 14.44.

```
<v:page name="demo_tree" xmlns:v="http://http://example.com/vspx/">
<html>
 <body>
 <v:form name="f1" method="POST" type="simple">
 <div>
 <v:tree name="tree1" multi-branch="1" orientation="vertical"
         root="root_node" start-path="." child-function="child_node" >
  <v:node-template name="node_tmpl">
    <div STYLE="margin-left:1em;">
        <v:button name="tree1_toggle" action="simple" style="image" value="--case (control.vc_parent as v
        <b><v:label name="label1" value="--(control.vc_parent as vspx_tree_node).tn_value" /></b>
        <v:node />
    </div>
  </v:node-template>
  <v:leaf-template name="leaf_tmpl">
    <div STYLE="margin-left:1em;">
        <v:label name="label2" value="--(control.vc_parent as vspx_tree_node).tn_value" />
    </div>
  </v:leaf-template>
 </v:tree>
 </div>
 </v:form>
 </body>
</html>
</v:page>
```

Description

Dynamic data bindable hypertext link.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

column = SqlName . The name of the column bound. If nothing else is specified, the column meta data from the containing update form sets the field's attributes.

null-value. This value will be shown if value of the column is NULL, also value of the control will be set to null if this value is passed upon POST request.

value = CalculateableValue . Data bindable value of control, represents value of HTML control to be drawn. The calculated value of this attribute is stored in the control in ufl_value field.

element-value = CalculateableValue . An XML entity that contains a value to be displayed by an HTML control. The calculated value is stored in ufl_element_value field of the control. This value is used only if ufl_value is null (e.g. if the 'value' attribute is not set at all), and the method vc_get_value_from_element() will be used to calculate ufl_value based on ufl_element_value, ufl_element_path and ufl_element_place.

element-place = CalculateableValue . The place of actual data inside an XML element. The calculated value of this attribute is stored in ufl_element_place field of the control. This is to process XMLSchema-compatible data without writing extra code for handling NULL values. The XML element can contain the value to be bound in either attribute or in an inner text node. XMLSchema treats missing attributes as NULL values. missing text node as an empty string value and if 'xsi:nil' attribute is 'true' then inner text value is NULL no matter if there are any text nodes. These self-evident rules are convenient for XQuery data retrieval but not for data update: an result of some XQuery expression can point to data but not to a place where data should occur in the future. The use of 'element-place' allows to eliminate the problem. Attributes 'element-value', 'element-path' and 'element-update-path' may locate an element that is always present whereas 'element-place' describes where the desired datum will occur in the element. The value of this attribute should be a string of syntax '@attributename' or 'text()'. If this is '@attributename' then the effective bound value is a value of the specified attribute or NULL if the specified attribute is missing. On update, either the attribute is created/edited in order to set non-NULL value or the attribute is deleted in order to set NULL. If text() is specified then both text value of the element and the value of its 'xsi:nil' are properly handled on both data bind and update.

element-path = CalculateableValue . This is the path inside the entity that comes from 'element-value' attribute. The default path is 'self::node()'. This path is used to point precisely to an subentity that should actually be used for data binding. The calculated value of this attribute should be a string in XQuery syntax, and it is saved in ufl_element_path member of the control.

element-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if 'element-path' attribute is missing. The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_params member of the control.

element-update-path = CalculateableValue . Like the value of 'element-path', this is the path inside the entity that comes from 'element-value' attribute. The difference is that 'element-path' is used inside 'vc_get_value_from_element() during data-bind to set ufl_value based on ufl_element_value whereas 'element-update-path' is used during data update inside 'vc_put_value_to_element() in order to save data inside the document that is referenced by ufl_element_value. The default path for update is equal to the path for data bind, i.e. it is the value of the calculated 'element-path' attribute or 'self::node()'. The calculated value of 'element-update-path' should be a string in XQuery syntax, and it is saved in ufl_element_update_path member of the control.

element-update-params = CalculateableValue . This is the vector of parameter values of the path specified by 'element-update-path' attribute. The default is NULL indicating no parameters. The attribute is calculated but not used if

'element-update-path' attribute is missing (e.g. you should not try to specify 'element-path' without 'element-update-path' and both 'element-params' and 'element-update-params' in hope that values from 'element-update-params' will be passed to 'element-path' on update). The calculated value of this attribute should be either NULL or a vector of even length whose items are parameter names and parameter values; refer to the description of xquery_eval() function for more details. The value of the attribute is saved in ufl_element_update_params member of the control.

fmt-function = CalculateableValue . This is to convert the value that is bound to the control into a string to use during the rendering. The value of this attribute should be a name of function that takes a single argument of the type that matches the type of ufl_value and returns a string. If this is used then the value of 'cvt-function' should probably be a name of function that converts the string back to the desired data type. If a control supports 'format' attribute then the format is applied to the result of 'fmt-function', so the value returned by fmt-function may be e.g. an integer to be formatted by '%d' format. The calculated value of this attribute is stored in ufl_fmt_fn field of the control.

cvt-function = CalculateableValue . This is to convert a user input of type varchar into a value that should be stored in ufl_value (and e.g. placed into some database column by an update). The calculated value of this attribute is stored in ufl_cvt_fn field of the control. For more details, see the description of 'fmt_function' attribute above.

format. A sprintf format string for printing the value

url = CalculateableValue . A data bound value to be printed in place of href attribute.

active = CalculateableValue . A data bound value to enable or disable the url. The default is '1' meaning 'enable'.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_url

```
create type vspx_url under vspx_field
as
  (
    vu_format varchar default '%s',
    vu_url varchar default '',
    vu_l_pars varchar default '',
    vu_is_local int default 0
  )
temporary self as ref
overriding method vc_render () returns any,
constructor method vspx_url (name varchar, parent vspx_control)
```

Examples

Example 14.45. Simple dynamic link

This draws an anchor in browser screen.

```
<v:page name="url__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head><title>VSPX samples | v:url</title></head>
    <body>
        <v:url name="url0" value="--'index'" url="--'index.vspx'" format="A link to page with name %s and
    </body>
  </html>
</v:page>
```

validator

validator — A validator that is applied to user input.

Synopsis

<**validator** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
test (required) ,
min (optional) ,
max (optional) ,
regexp (optional) ,
expression (optional) ,
empty-allowed (optional) ,
message (optional) ,
runat (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

The validator objects are invoked when the element's control gets posted. the validator elements only make sense inside field or form types of controls. the validators are invoked in the order given, and the first one to fail stops the invocation chain, so that no later ones are attempted. furthermore the vc_is_valid member of the containing page class instance will be reset to false (0) to stop further processing. see also error-summary element and error-glyph attribute of field element.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the

name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

test. The type of test to be performed, can be 'length', 'value', 'regexp' or 'sql'.

min. A lower limit in value and length tests

max. The upper limit for value and length tests

regexp. The REGEXP pattern to match field value

expression. A SQL expression for validation

empty-allowed. If specified as true (1) this will allow submitting an empty field

message. The error message to be associated to parent control when the test represented by this validator fails.

runat. Where to perform validation, at server side after posting, or at browser side when entering the values. Note that client side validators can be assigned only to input controls, hence client side form validators for inter-field integrity testing are not allowed.

Client side validators will generate client side JavaScript.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_validator

Examples

Example 14.46. Validation of text area input

The form contains a v:textarea control with v:validator assigned. When the OK button is pressed, data are posted back to the same URI so the page is instantiated again. If validator found a violation, the message is shown right after the text input. (The error reporting may be changed by using v:error-summary VSPX control and by adding 'error-glyph' attribute to the v:textarea.)

```
<v:page name="validator__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:validator</title>
    </head>
    <body>
      <v:form name="form1" type="simple" action="" method="POST">
        <v:textarea name="ta1" default="enter your text here" value="--coalesce ({?'ta1'}, control.ufl_va
          <v:validator test="length" min="0" max="50" message="The input length should not exceed 50 char
        </v:textarea>
        <v:button name="submit1" action="simple" value="OK"/>
      </v:form>
    </body>
  </html>
</v:page>
```

VX-S-2

variable

variable — Page variable - a user defined member of page class.

Synopsis

<variable /> (
name (required) ,
type (required) ,
default (optional) ,
persist (optional) ,
param-name (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This element declares a data member for the page subclass corresponding to the containing page. The value of this data member can be preserved between consecutive postbacks. The attribute "persist" determine how to save the variable's value: to session table for inter-page usage, keep in page state only or do not keep it at all. Note that inter-page variable storage is available only when a vspx:login control is included on the page and authentication is performed; also the name of page variables in corresponding pages needs to be same. There is no special class for this control because only a data member will be added. Also the page defines two special variables 'sid' and 'realm' for login control. So when an existing login control is is in authenticated state, these will contain values for session id and application realm. Also every non-repeating control of the page will be represented as a page variable and thus be acessible as 'self.<name_of_control>' anywhere in the VSPX page after page initialization.

Attributes

name = SqlName . The name of page class member.

type = SqlName . The SQL data type of the variable.

default = SqlCode . The default value. Must be a literal scalar value suitable for the default clause of a user defined type member.

persist.

Table 14.13. Allowed values of the 'persist' attribute

session	keep the variable in the session; needs a login control to be present
pagestate	keep the variable in page view state
temp	do not keep variable
0	same as 'pagestate'
1	same as 'session'

param-name = SqlName . This specifies an optional name of a URL parameter for setting the page variable value. When this is specified and there is a parameter matching the name, the variable is set after it. This is a shorthand for an explicit call of keyword_get.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Examples

Example 14.47. Declaration of page variable

The v:variable element defines a new member of page class and hance we can access it with self.mask in rest of VSPX code.

```
<v:page name="variable__0" xmlns:v="http://http://example.com/vspx/">
  <html>
    <head>
      <title>VSPX samples | v:variable</title>
    </head>
    <body>
      <v:variable name="mask" type="varchar" default="null"/>
      <?vsp self.mask := 'first value'; ?>
      <p>The variable value is set to '<?V self.mask ?>'</p>
      <?vsp self.mask := 'second value'; ?>
      <p>The variable value is set to '<?V self.mask ?>'</p>
    </body>
  </html>
</v:page>
```

vscx

vscx

Synopsis

<**vscx** /> (
name (required) ,
annotation (optional) ,
initial-enable (optional) ,
enabled (optional) ,
instantiate (optional) ,
control-udt (optional) ,
xsd-stub-xhtml (optional) ,
width (optional) ,
height (optional) ,
url (required) ,
debug-srcfile (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

Custom control encapsulated in a separate VSPX page. This is a wrapper for custom control instantiation. The target URL MUST contain a valid VSPX page reference. In this way repeatable pieces of code can be reused in form of instantiation of their page class, this is different from inclusion. The target page variables can be initialized as attributes in this control, where name of attribute is a name of variable of target page and value is an expression to be assigned.

Attributes

name = SqlName . A page level unique name identifying a control.

annotation. A human readable comment.

initial-enable = CalculateableValue . Determines whether a control is initially visible. True by default. Could be data-bound to an SQL expression.

enabled = CalculateableValue . Determines whether a control is visible. True by default. Could be data-bound to an SQL expression.

instantiate = CalculateableValue . Determines whether a control instantiate its children. It is true by default. It could be data-bound to an SQL expression. Unlike most of calcucateable attributes, the value of this attribute for a control is calcluated before calling 'on-init' event handler of the control; other values are calculated before calling 'before-data-bind' event handler.

control-udt = SqlName . At run time every control is represented as an instance of some user-defined type (UDT). VSPX compiles selects the UDT to use depending on name of the XML element that represents the control and maybe some of its attributes. In some specific cases the application developer may instruct VSPX compiler to use some other UDT, e.g. an application-specific UDT that is derived from the preset one. If specified, the value of 'control-udt' attribute should be equal to the name of the desired target UDT.

xsd-stub-xhtml. This attribute is for internal use only. It has no effect if added to the source VSPX file.

width. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of this attribute will not be used when the resulting HTML is rendered.

height. Visible width of the control when it is displayed in WYSIWYG tools when the source VSPX text is edited. The value of

this attribute will not be used when the resulting HTML is rendered.

url. Reference to a VSPX page to be instantiated as a control.

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_vscx

```
create type vspx_vscx under vspx_form
self as ref temporary
constructor method vspx_vscx (name varchar, parent vspx_control, uri varchar),
overriding method vc_pre_render (stream any, n int) returns any
```

Examples

Example 14.48. Outer page, including a navigation bar via vscx__1.vspx

This page will embed another page twice, but not as simple inclusion. The second page is treated as a control and it's page class will be instantiated twice as as a child of outer page.

```
<v:page name="outer_page" xmlns:v="http://http://example.com/vspx/">
  <html>
    <body>
      <v:variable name="var1" type="int" default="0" />
      <h3>Embeeding a page as a custom control</h3>
      <v:form type="simple" name="f1">
        <div>
          <div>control1</div>
          <v:vscx name="bar1" url="vscx__1.vspx"/>
        </div>
        <div>
          <div>control2</div>
          <v:vscx name="bar2" url="vscx__1.vspx"/>
        </div>
        <div>
          <v:text name="txt2" />
          <v:button action="simple" value="Outer" name="b2" />
        </div>
      </v:form>
    </body>
  </html>
</v:page>
```

Example 14.49. Simple navigation bar used as custom control

This page is used inside vscx__0.vspx one as a custom control.

```
<v:page name="custom_bar" xmlns:v="http://http://example.com/vspx/">
  <v:variable name="test" type="int" default="12" />
  <table border="1" cellspacing="1" cellpadding="0">
    <tr>
      <td>
        <v:url name="u1" value="Home" url="--http_path ()" /> |
      </td>
      <td>
        <v:url name="u2" value="Settings" url="--http_path ()||'?settings'" /> |
      </td>
      <td>
        <v:url name="u3" value="Posts" url="--http_path ()||'?posts'" /> |
      </td>
      <td>
        <v:url name="u4" value="Maintenance" url="--http_path ()||'?maint'" />
```

```
        </td>
      </tr>
    </table>
    <div>
      <v:form type="simple" name="f1">
        <v:text name="txt1" />
        <v:button name="b1" action="simple" value="Inner"/>
      </v:form>
    </div>
  </v:page>
```

xsd-stub

xsd-stub — This is for internal use only.

Synopsis

<**xsd-stub** /> (*debug-srcfile* (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control should never appear in the VSPX source. It is for internal use only. Before applying XML schema validation to the page, Virtuoso replaces non-VSPX tags with this one when they reside inside v:page.

Attributes

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_xsd_stub

```
create type vspx_xsd_stub under vspx_control
as ( vc_stub any ) temporary self as ref
```

xsd-stub-script

xsd-stub-script — This is for internal use only.

Synopsis

<**xsd-stub-script** /> (*debug-srcfile* (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control should never appear in the VSPX source. It is for internal use only. Before applying XML schema validation to the page, Virtuoso replaces non-VSPX tags with this one when they reside inside event script tag such as v:on-init.

Attributes

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_xsd_stub_script

```
create type vspx_xsd_stub_script under vspx_control
as ( vc_stub any ) temporary self as ref
```

xsd-stub-top

xsd-stub-top — This is for internal use only.

Synopsis

<**xsd-stub-top** /> (*debug-srcfile* (optional) ,
debug-srcline (optional) ,
debug-log (optional)) ;

Description

This control should never appear in the VSPX source. It is for internal use only. Before applying XML schema validation to the page, Virtuoso replaces non-VSPX tags with this one when they reside outside v:page.

Attributes

debug-srcfile. URI of the source document where the tag comes from.

debug-srcline. Line number in the source document where the tag comes from.

debug-log. This defines what sort of data are saved to the debugging log.

Declaration of type vspx_xsd_stub_top

```
create type vspx_xsd_stub_top under vspx_control
as ( vc_stub any ) temporary self as ref
```

14.4.10. XForms rendering

The VSPX form controls such as form, button, select-list, text etc. can be rendered as XForms analogues using a special connection variable 'RenderXForms' set to true (integer 1). Also XML post data coming from XForms capable agents will be parsed and provided to the VSPX page methods in usual form (name/value array). The HTML form elements substitution to the XForms is as follows: input type="text" - xforms:input; input type="password" - xforms:secret; textarea - xforms:textarea; select - xforms:select1; select multiple - xforms:select; checkbox - xforms:input (of datatype boolean); input type="radio" - xforms:select1 appearance="full"; input type="submit" - xforms:submit; form - xforms:model. Furthermore validators which belongs to a input elements (not to a containers) will enforce XMLSchema types of the XForms model. Note that some XForms agents may need special object registering or a special Content-Type reported, so as this varies from agent to agent the application logic is responsible for setting them properly.

```
<v:page xmlns:v="http://example.com/vspx/" name="xform_demo">
    <v:on-init>
        -- enable XForms rendering
        connection_set ('RenderXForms', 1);
    </v:on-init>
    ... page content follows ...
</v:page>
```

14.4.11. XMLSchema for VSPX page

```
<?xml version="1.0" encoding="UTF-8"?>
<xs:schema targetNamespace="http://example.com/vspx/" xmlns:v="http://example.com/vspx/" xmlns:xs="http:/
  <xs:simpleType name="CalculateableValue" final="restriction">
    <xs:restriction base="xs:string">
      <xs:whiteSpace value="preserve"/>
    </xs:restriction>
  </xs:simpleType>
  <xs:simpleType name="ButtonStyle" final="restriction">
    <xs:restriction base="xs:string">
      <xs:enumeration value="submit"/>
      <xs:enumeration value="url"/>
      <xs:enumeration value="image"/>
    </xs:restriction>
  </xs:simpleType>
  <xs:simpleType name="ButtonAction" final="restriction">

      <xs:attribute name="initial-offset" type="v:CalculateableValue" use="required"/>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

14.5. Deploying ASP.Net Web Applications

Virtuoso is a CLR host. It is responsible for initializing the runtime, defining the application domain (its runtime boundaries, security settings, etc), and executing user code within such domains. Windows can be used as the development platform, a very developer friendly environment with a rich set of tools, but you will not be restricted to Windows, .NET and IIS to run the assemblies produced. Where .NET is not readily available or desired Virtuoso contains Mono, an open source re-implementation of Microsoft .NET, a vehicle taking .NET cross-platform.

The CLR run-time is a part of the Virtuoso process. The Mono run time may be run either as in-process or as out-of-process. Hosted applications can make use of the regular Virtuoso .Net data provider to access Virtuoso SQL data and procedures. Microsoft ASPX files can also be run directly from Virtuoso either from the file system or WebDAV. Each of these capabilities releases you from the Microsoft platforms without compromising your development platform.

The Virtuoso CLR hosting is implemented using the VSEI.

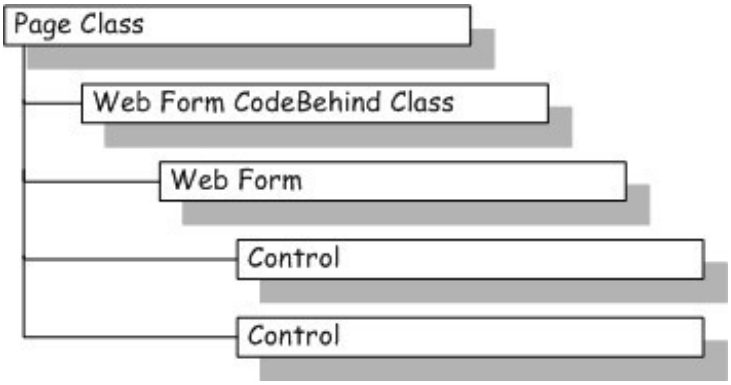
14.5.1. Programming Concepts

ASP.Net Web Forms are divided into two sections: the user interface and the application logic. The user interface comprises HTML markup and ASP.Net web controls whereas the application logic contains all the programming code that allows the controls to interact with themselves and the server back-end. This provides the level of abstractions required for dynamic efficient Web application design. The interface can be altered without any backward or forward dependence on the code (logic). The Web Form interface should be created with the .aspx extension. The application logic can be contained in-line within the ASPX application, but developers should strive to keep the code in a separate location known as the "CodeBehind". This is a file that contains the logic (code) for the Web Form which should end in an extension appropriate for the programming language used, such as .vb for Visual Basic or .cs for C#. The CodeBehind can be written in any language for which there is a .Net compiler for. The compiler generates bytecode that can be deployed anywhere the .Net runtime exists.

The ASPX Web Form is compiled into an object that takes its place on a tree of controls and classes. The CodeBehind is compiled into an object on this tree when the page is requested. The Web Form must inherit from a "base-class" defined in the CodeBehind class file.

Figure 14.17. ASPX Web Form class hierarchy



Now we will create a new Web Form containing an HTML heading and an ASP.Net DataGrid control that will display results from the local Virtuoso server.

Example 14.50. Sample .Net Web Application: VirtTest.aspx

```
<%@ Page Language="vb" Inherits="VirtTest" Src="VirtTest.aspx.vb" %>
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0 Transitional//EN">
<html>
        <head>
                <title>Virtuoso Provider to DataGrid in VB</title>
        </head>
        <body>
        <h1>Simple VB Virtuoso DataBinding Demo</h1>
                <form
xml:id="form1" method="post" runat="server">
                        <asp:DataGrid id=DataGrid1 runat="server" DataMember="Customers"
                                BorderColor="silver"
                                BorderWidth="1"
                                CellPadding="2"
                                Font-Name="Tahoma"
                                Font-Size="10pt">
                          <HeaderStyle BackColor="#2222ff" ForeColor="yellow"/>
                          <PagerStyle Mode="NextPrev" />
                        </asp:DataGrid>
                </form>
        <hr>
        </body>
</html>
```

On the first line of the file we use the `@ page` directive to inherit the CodeBehind class we will create in the CodeBehind file. The source of which can be optionally declared here with the `Src=` attribute. Visual Studio makes use of `CodeBehind=` for tracking associated source code instead. If either of these two attributes are specified then the .Net runtime will attempt to compile the code into an assembly (DLL) upon first execution if it does not already exist or seems out-of-date. The following code fragment is the CodeBehind, VirtTest.aspx.vb.

Now we want some logic behind the Web Form. We have placed a DataGrid control on a web page but we need to supply data to it now:

Example 14.51. Sample .Net Web Application CodeBehind: VirtTest.aspx.vb

```
imports System
imports System.Web
imports System.Web.UI
imports System.Web.UI.WebControls
imports System.Web.UI.HtmlControls
imports System.Data

imports OpenLink.Data.VirtuosoClient

Public Class VirtTest
    Inherits Page
```

```
    Protected WithEvents myConnection As OpenLink.Data.VirtuosoClient.VirtuosoConnection
    Protected WithEvents myCommand As OpenLink.Data.VirtuosoClient.VirtuosoDataAdapter
    Protected WithEvents DataGrid1 As System.Web.UI.WebControls.DataGrid
    Protected WithEvents ds As System.Data.DataSet

    Private Sub Page_Load(sender As Object, e As EventArgs) Handles MyBase.Load
        Dim myConnection As new VirtuosoConnection("HOST=noodle:1112;UID=dba;PWD=dba;Database=Demo")
        Dim myCommand As new VirtuosoDataAdapter("select * from Demo..Customers", myConnection)

            Dim ds As new DataSet()
        myCommand.Fill(ds, "Customers")

        DataGrid1.DataSource=ds.Tables("Customers")
        DataGrid1.DataBind()

    End Sub

End Class
```

This file is compiled using the following command (split across lines for readability and would otherwise all be on one line):

```
E:\myweb\myapp>
  vbc /target:library
    /r:System.dll
    /r: System.Web.dll
    /r:System.Data.dll
    /r:OpenLink.Data.VirtuosoClient.dll
    /r:System.Xml.dll
    /out:bin\VirtTest.dll
    VirtTest.aspx.vb
```

Once compiled, the resulting DLL library should be in the bin subdirectory of the application root. When the assembly is available in this way the .aspx file does not need to contain the `Src=` attribute since there will be no need to compile the CodeBehind. If the `Src=` attribute is specified in the .aspx file but the CodeBehind file is not located on the server then an error will be signalled indicating that a required resource cannot be found, because the CodeBehind class is compiled on demand.

14.5.2. ASP.Net Deployment & Configuration

ASP.Net allows multiple Web applications to run on the same machine independently of each other. Web applications have their own directory for components (the ".\bin" directory) and its own XML-based configuration file (the ".config" file). This allows us to develop robust applications using custom configurations and components (or different versions of components) for each one.

Note:

The ASP.Net machine-wide configuration is held in machine.config found in the `(C:\Winnt\Microsoft.NET\)Framework\[version number]\CONFIG directory` depending on your installation. Applications hosting or making use of .Net may have an application configuration [App Name].config. Web applications store their individual configurations in Web.config stored in the Web application root directory.

Each ASP.Net application uses a local assembly cache to hold application specific logic (assemblies, contained in compiled DLLs). The \bin directory located in the application root is the local assembly cache for Web applications. This directory is denied access directly from browsers. This prevents users from downloading or executing any DLLs contained within.

When a Web application is started the .Net Framework constructs a new instance of the `System.AppDomain` class. When the instance is constructed it creates in-memory shadow copies of the DLLs in the \bin directory. The .Net Framework keeps an in-memory cache (shadow) of all assemblies used so that the actual files (.DLLs) are not locked. The .Net Framework will monitor the original DLL for changes. When changes occur the in-memory cache is updated. Applications already loaded and running with calls in-progress to the old library will continue using the old version so there is no interruption. All new calls to library will be effected, and use the new library. This means that you are free to replace the DLL with new versions as required. Previously with ASP you were required to stop IIS, register the DLL with RegServ32.exe and restart the Web server.

When new libraries are added to the .Net Framework for use in any application system wide, such as the Virtuoso Data Provider, these need to be added to the Global Assembly Cache (GAC). This is achieved using the `gacutil.exe` utility found in the `Framework\[version number]` directory. The `gacutil.exe` tool registers the DLL along with its version. One of .Net's strengths is its ability to maintain multiple versions of DLLs for multiple applications. This prevents "DLL-hell"; new DLLs

breaking old applications. Applications can also maintain their own local versions of DLLs in their \bin directory.

```
gacutil.exe /i <full path and file name>.dll
```

Registers assemblies with the Global Assembly Cache.

```
gacutil.exe /l
```

Can be used to list registered assemblies.

After registering assemblies using the `gacutil.exe` tool you must add an `<add assembly="..." />` entry into the `<configuration><system.web><compilation><assemblies>` section of the machine.config.

The application given in the previous section can be deployed to Virtuoso in the WebDAV repository or directly on file system under the VSPRoot directory. You should copy the directory structure as defined, applications in the root of the new directory and DLLs in a bin subdirectory. A virtual directory must be configured with execute permissions enabled. The application can be tested with a Web browser.

14.5.3. The Mono Project

The Mono Project is an open source version of the Microsoft.NET development platform. Incorporating key .NET compliant components, including a C# compiler, a Common Language Runtime just-in-time compiler, and a full suite of class libraries, the Mono Project will enable developers to create .NET applications and run them on Windows or any Mono-supported platform. Besides greatly improving the efficiency of development in the open source world, the Mono Project will allow the creation of operating-system-independent programs. Although primarily developed on Linux, Mono is being ported to as many operating systems as possible.

Microsoft.NET development tools, which include the C# compiler and Common Language Infrastructure (CLI), let programs written in C# and other languages run on non-Windows operating systems. The Mono Project development platform provides open source developers with a true "build once, deploy anywhere" tool-set taking advantage of the myriad of services enabled by Microsoft.NET.

The Mono Project will provide three key elements in a development framework designed to allow developers to quickly create, deploy and run .NET compatible applications on non-Windows platform. A C# compiler extending the GNOME development platform will allow Linux developers to create .NET compatible applications. These developers will also be able to build upon a complete implementation of class libraries compatible with the Microsoft CLI, enabling developers to create end-user applications as well as powerful web services using the database functionality available on open source systems. Portation of Mono yields versions of the Microsoft Common Language Run-Time (CLR) just-in-time (JIT) run-time engine will allow non-Windows systems to run .NET applications built on Windows, Linux or UNIX platforms.

The example in the previous section can be run using the CLR hosting ability of Virtuoso, but only with the precompiled assembly which has to be deployed into the Mono/lib directory of the Mono installation.

The Virtuoso installer on non-Windows platforms for which there is a port of Mono available installs the latest Mono CLR. This is required for the Virtuoso server to host .Net applications on non-Windows platforms.

Only a compiler for C#. Inline ASPX code using C# is a safe way to write and experience ASPX hosted from Virtuoso. Although this goes completely against the programming practice guidelines for .Net

The only permissible Application Domain is the Mono application. ASP.Net applications should have their own self containable Application Domain - the ./bin directory. Mono does not support this as of yet. The work around is to place all assemblies into the Mono domain.

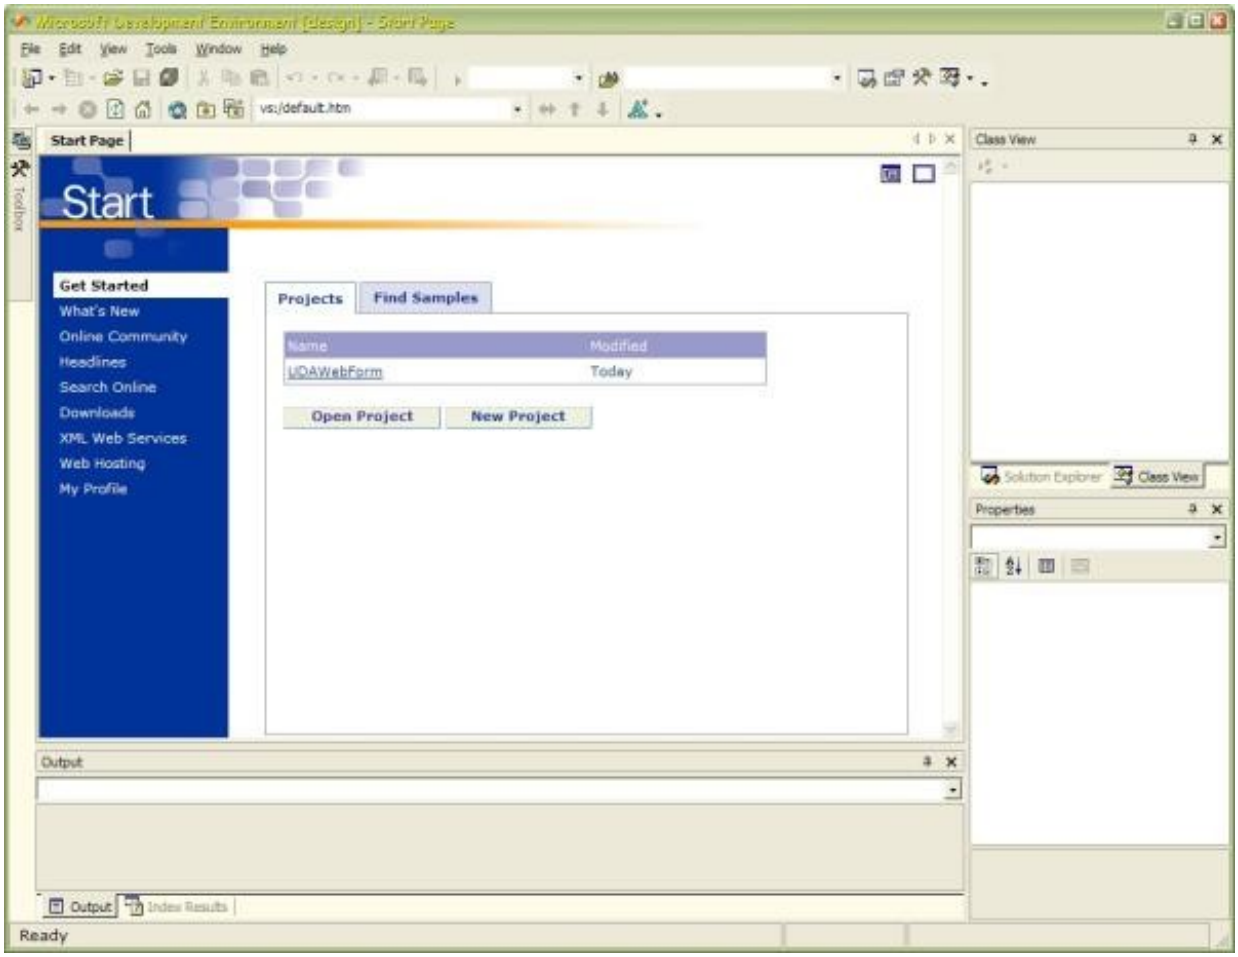
14.5.4. Migrating ASP.Net Applications to Virtuoso

Creating a Simple Data Bound Application

This section will describe how to use the MS Visual Studio to create an application using as much drag and drop as possible. We want to create a table of data in a web page from a database.

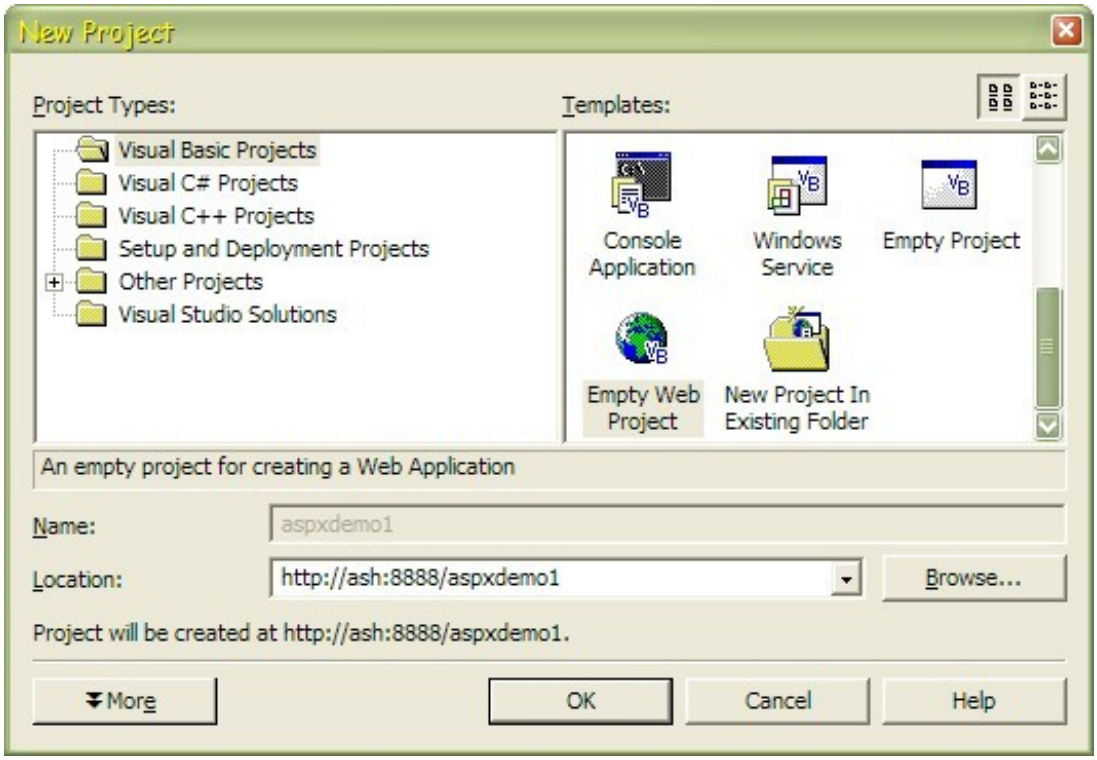
1. **Launch Microsoft's Visual Studio.** Once Visual Studio has been launch it present you with the start page that lets you create a New Project.

Figure 14.18. Databound Examples using MS Visual Studio



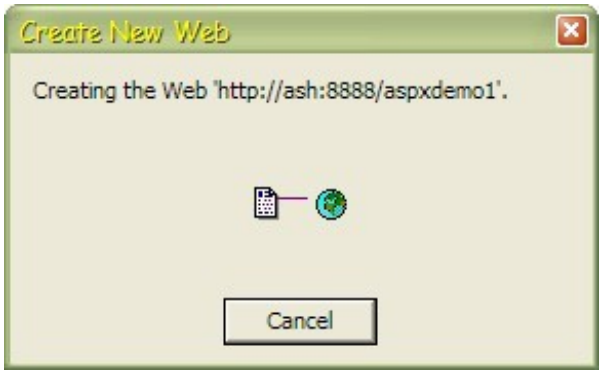
2. **Create a new Empty Web Project .** From the templates select a new Empty Web Project found in the Visual Basic Projects type. You must also select a location on an IIS web server.

Figure 14.19. Databound Examples using MS Visual Studio



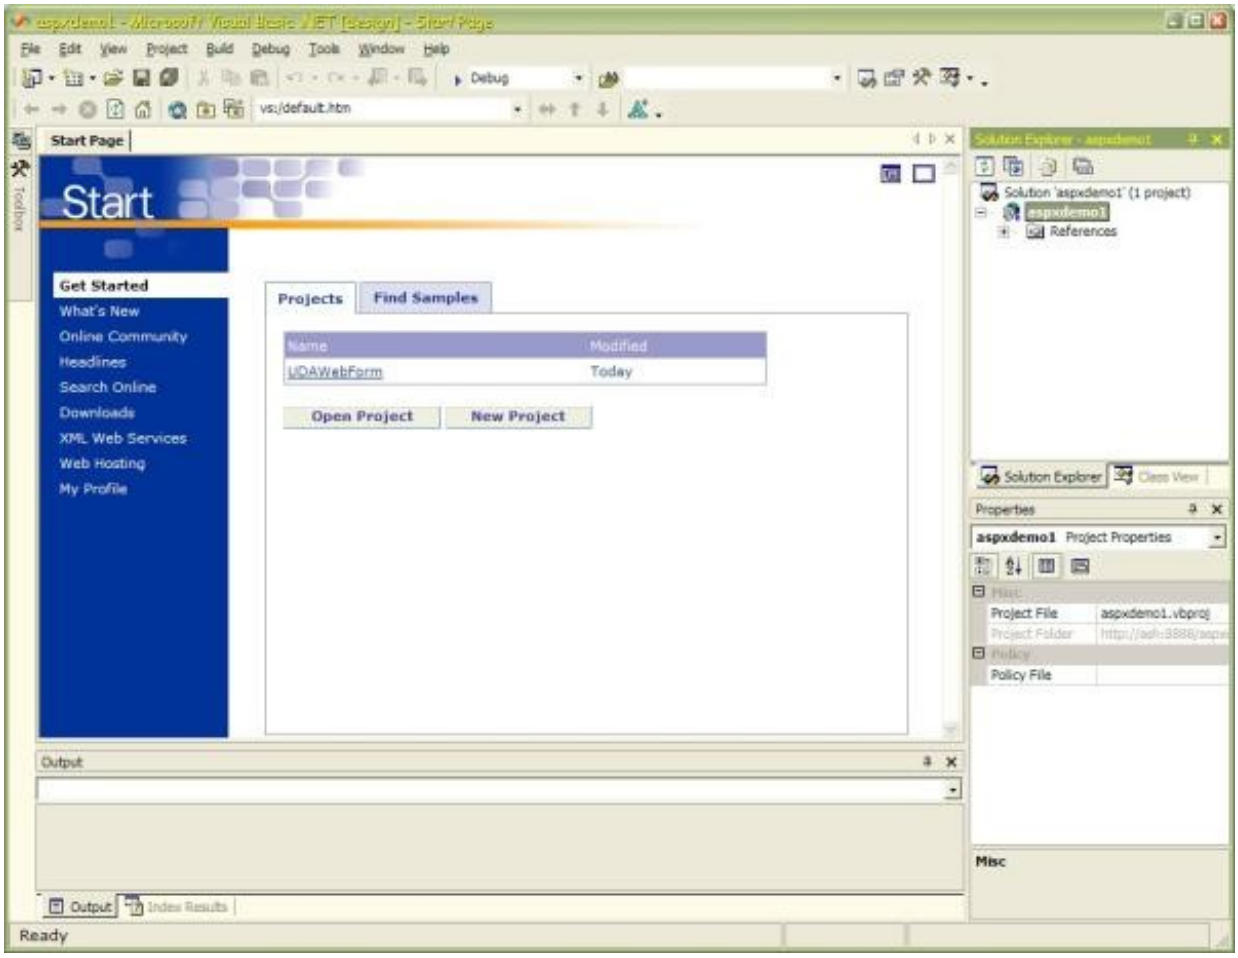
3. **Wait for IIS application to be set-up.** You will be shown a progress dialogue as Visual Studio contacts your web server creating a new web application there.

Figure 14.20. Databound Examples using MS Visual Studio



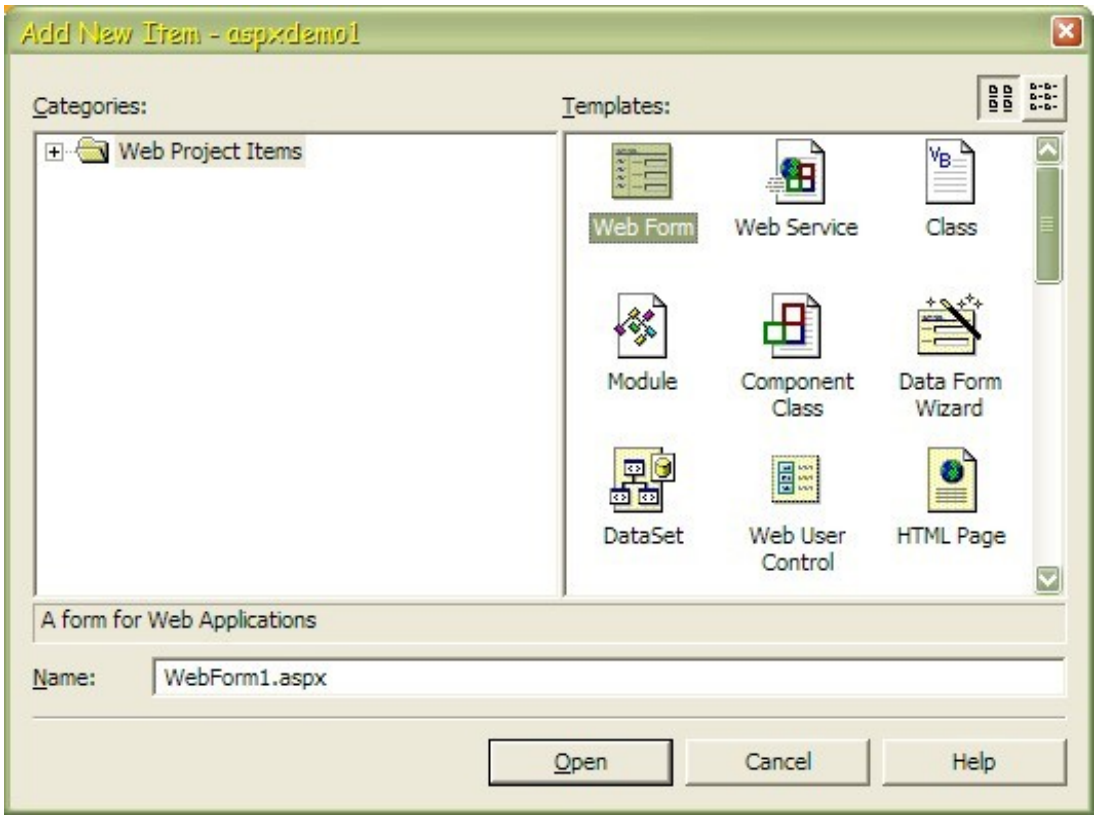
4. **Add New Web Form.** When the application-space has been configured on the web server you will be returned to the main Visual Studio windows. Now we must create our page. Right-click on the project name in the Solution Explorer and select Add New Web Form.

Figure 14.21. Databound Examples using MS Visual Studio



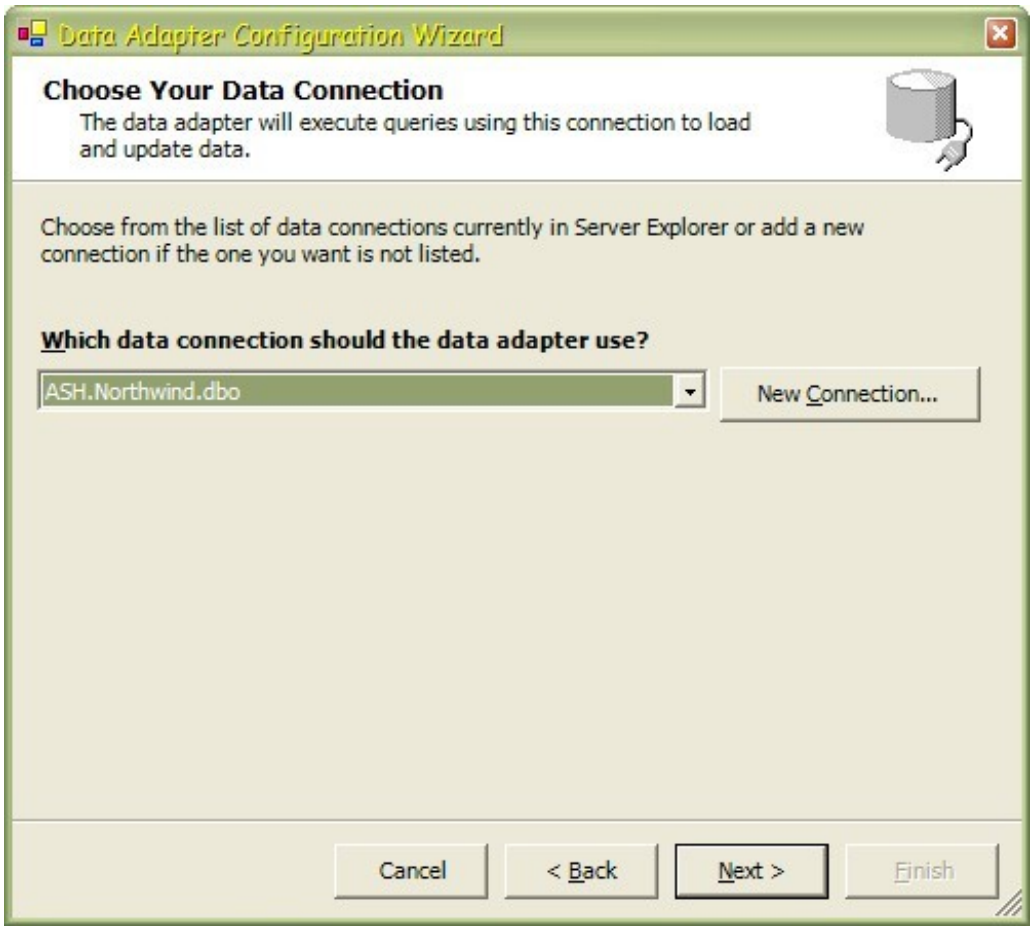
5. **New Web Form.** The Add New Item option will appear, automatically selecting the "Web Form" item to add. Supply a name for the page and click Open to begin.

Figure 14.22. Databound Examples using MS Visual Studio



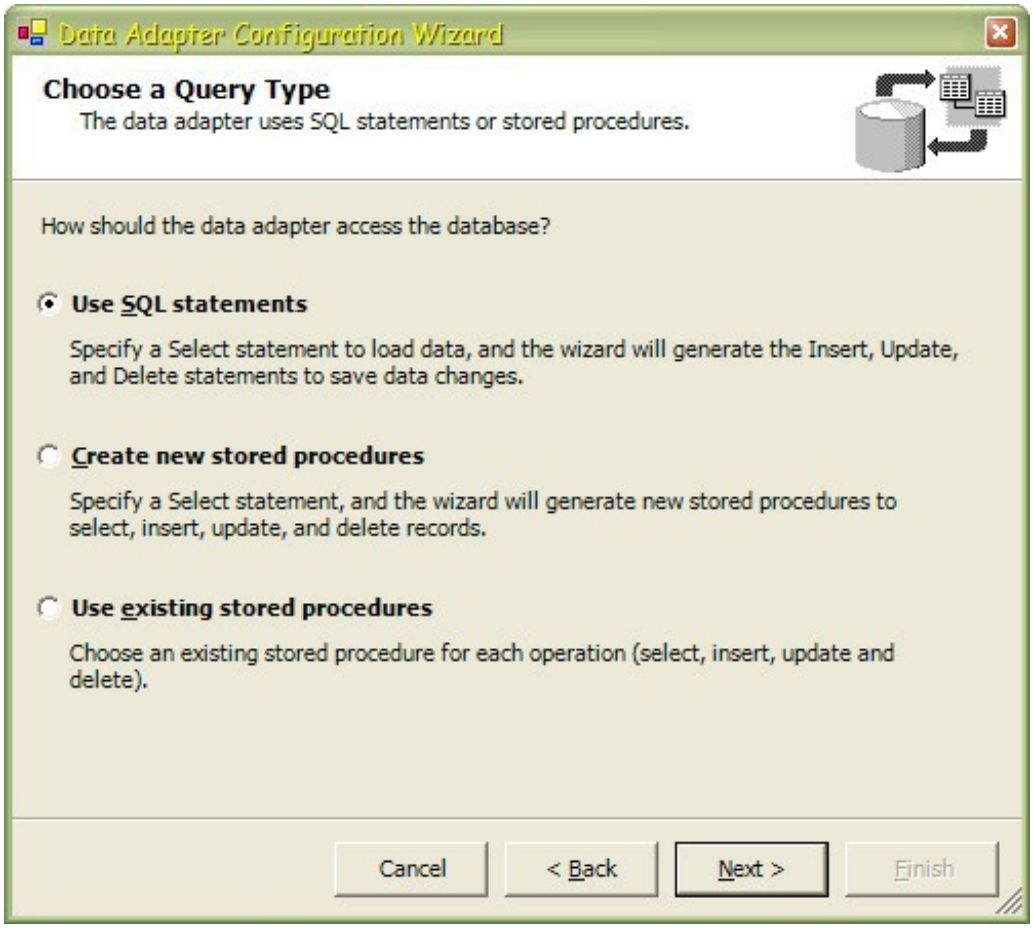
6. **Add a SqlDataAdapter Control.** With the fresh "Web Form" we can start. From the ToolBox double-click on the SqlDataAdapter in the Data panel. This will start the Data Adapter Configuration Wizard . After reading the description on the first panel click on the Next button. You will be asked to choose your connection. Assuming that you have access to a Northwind database hosted in MS SQLServer you can either make use of an existing connection to it or configure a new one using the New Connection button. Pressing the New Connection button will present the normal OLEDB dialogues for creating a new datasource. Once a data connection has been selected press Next to continue.

Figure 14.23. Databound Examples using MS Visual Studio



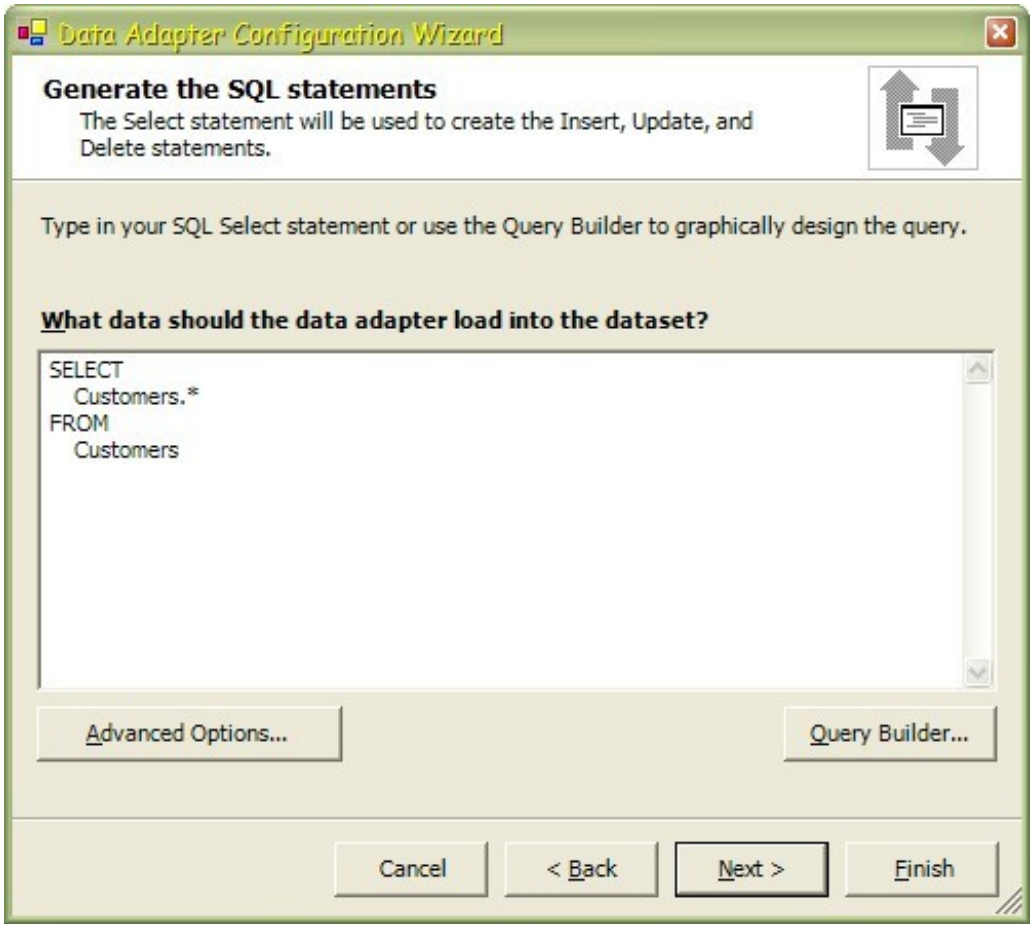
7. **Choose a Query Type.** The next panel will ask how the data adapter should access the database. For simplicity we will stick with the default of Use SQL Statements. Press Next.

Figure 14.24. Databound Examples using MS Visual Studio



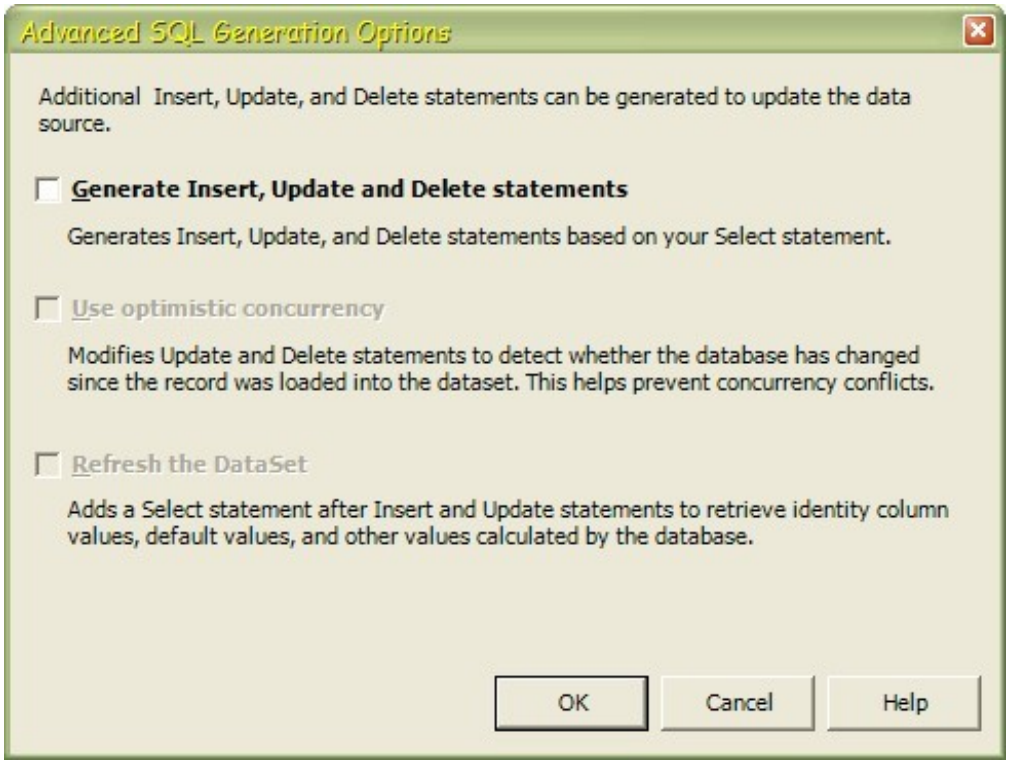
8. **Generate SQL Statements.** At this point you can either type a SQL statement if you know exactly what you are looking to get back from the database, or you can use the Query Builder to point-and-click to your data. In our case we will retrieve everything from the Customers table using a simple query:`select * from Customers`.

Figure 14.25. Databound Examples using MS Visual Studio



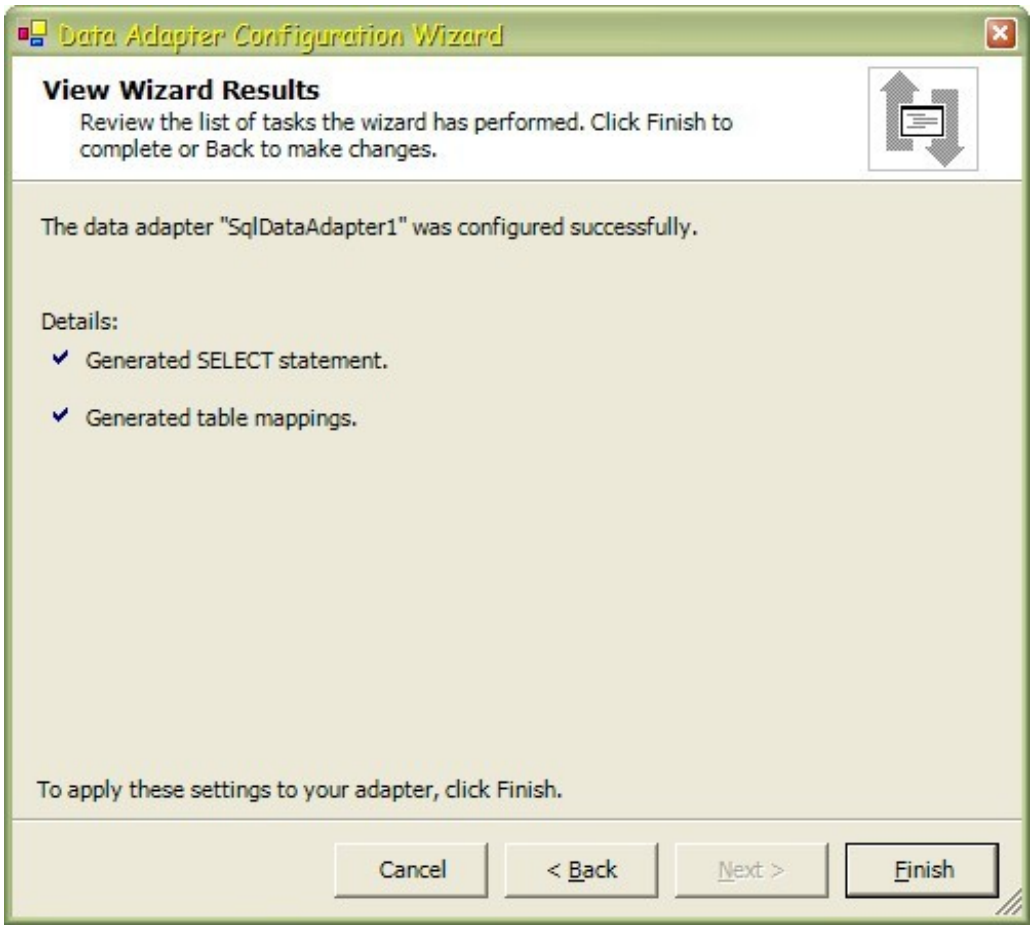
9. **Advanced Options.** Click on the Advanced Options button. Unselect the top checkbox. This will also unselect the other two automatically. We will not be performing any updates in this example. OK the advanced options, upon return to the main dialogue press the Next button to continue onwards.

Figure 14.26. Databound Examples using MS Visual Studio



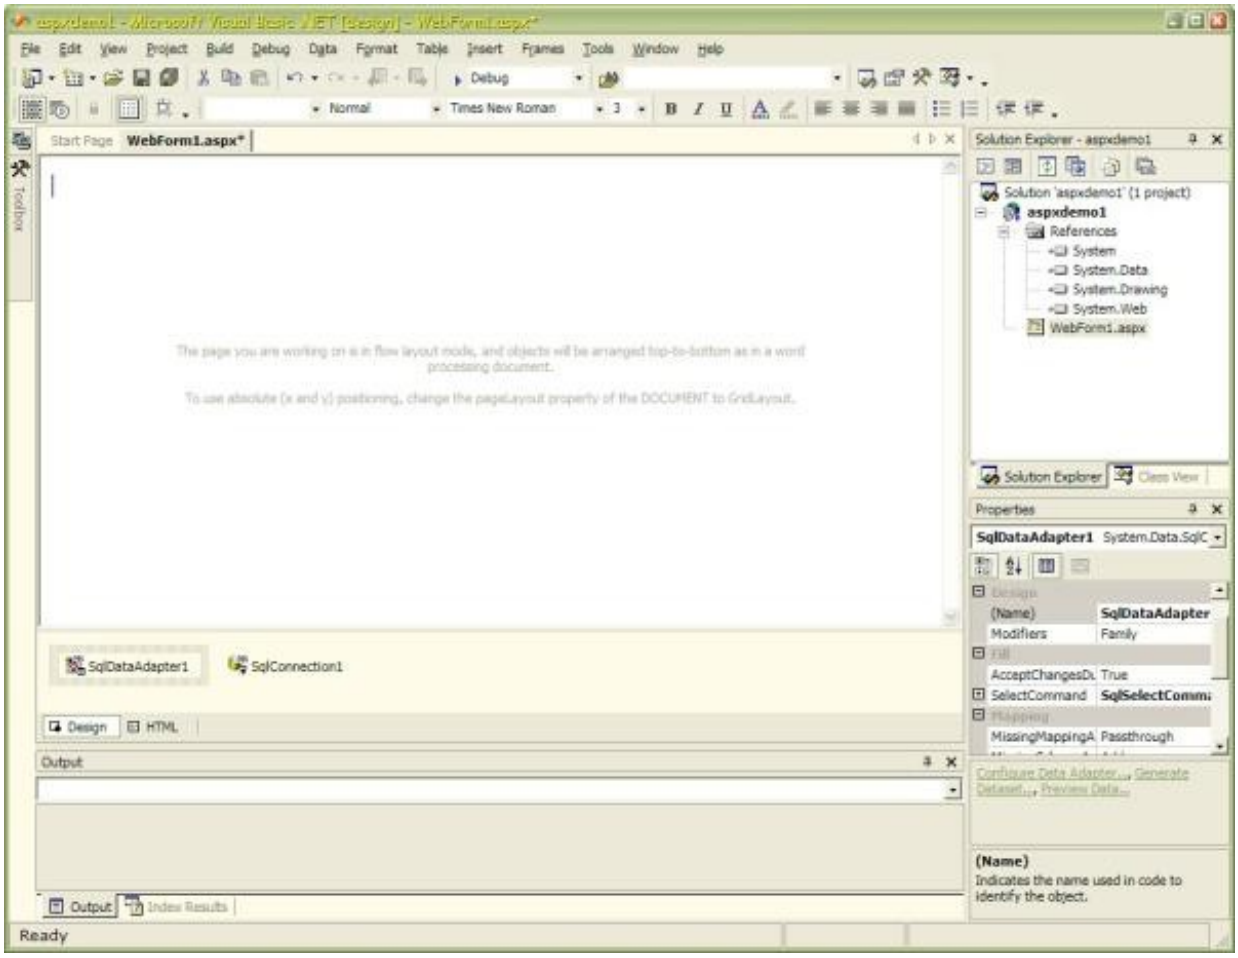
10. **View Wizard Results.** The next panel confirms all the options selected leaving us to simply complete the wizard.

Figure 14.27. Databound Examples using MS Visual Studio



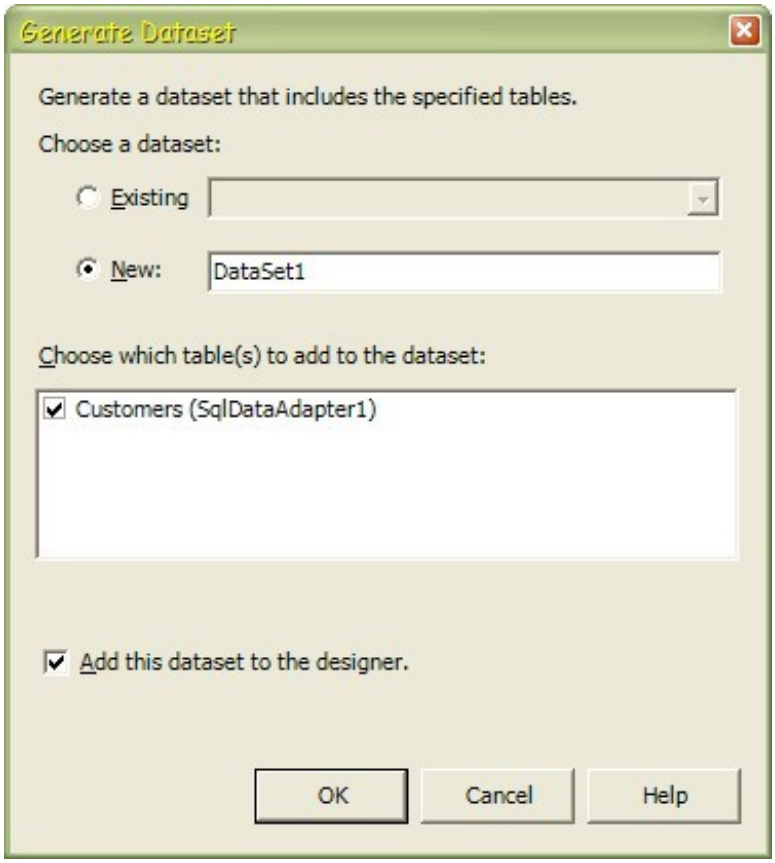
11. **Back to the main window...** When the wizard finishes and returns you to the main Visual Studio window you will see that two controls have been added to the Web Form. The connection control has been automatically generated to support the Data Adapter.

Figure 14.28. Databound Examples using MS Visual Studio



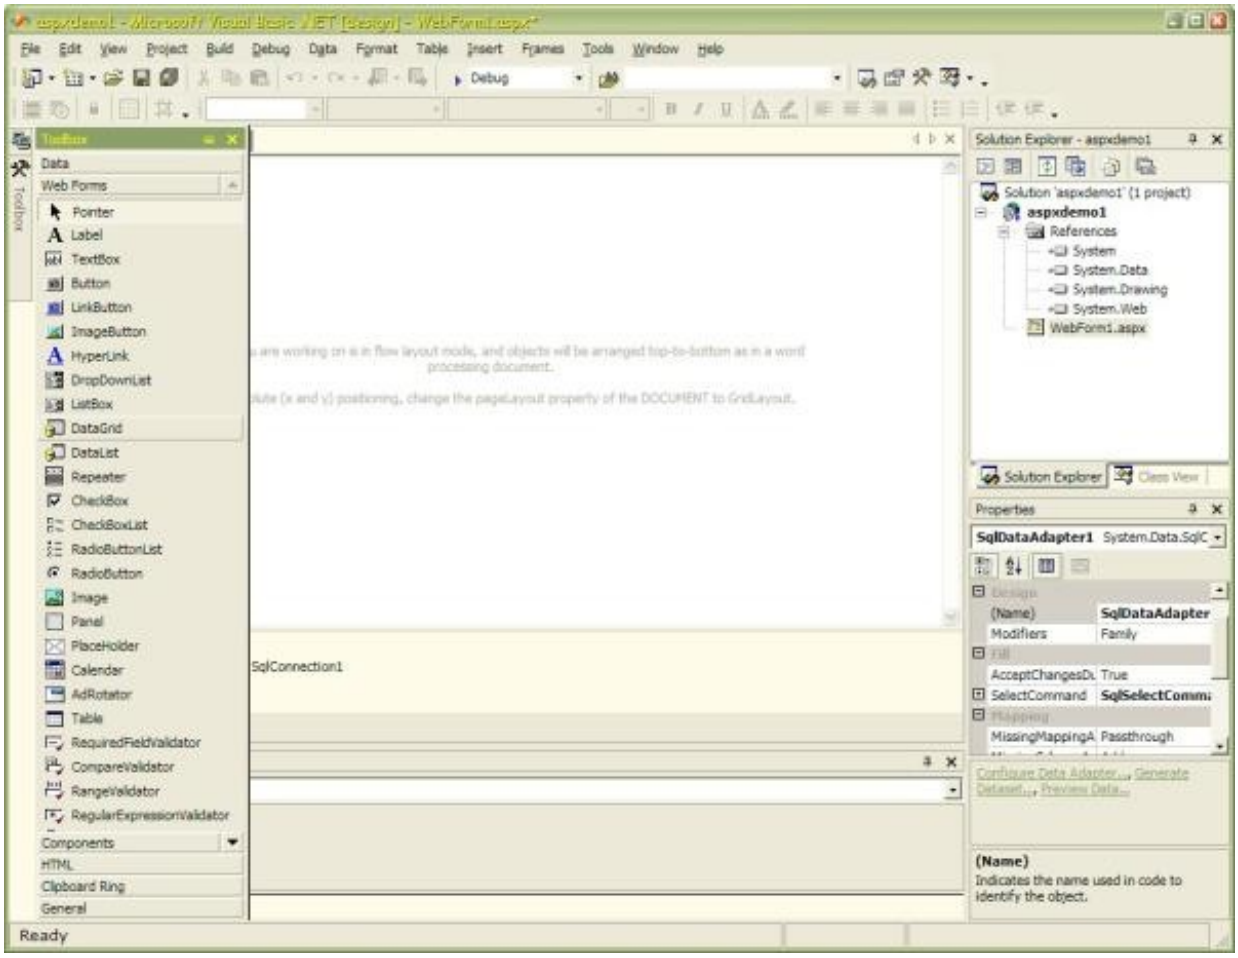
12. **Generate Dataset.** Before we can display anything on the page we need to form a Dataset. Right-click on the SQLDataAdapter1 control you previously added and select Generate Dataset. Defaults on the displayed dialog are all sufficient. After verifying them click the OK button to generate the dataset.

Figure 14.29. Databound Examples using MS Visual Studio



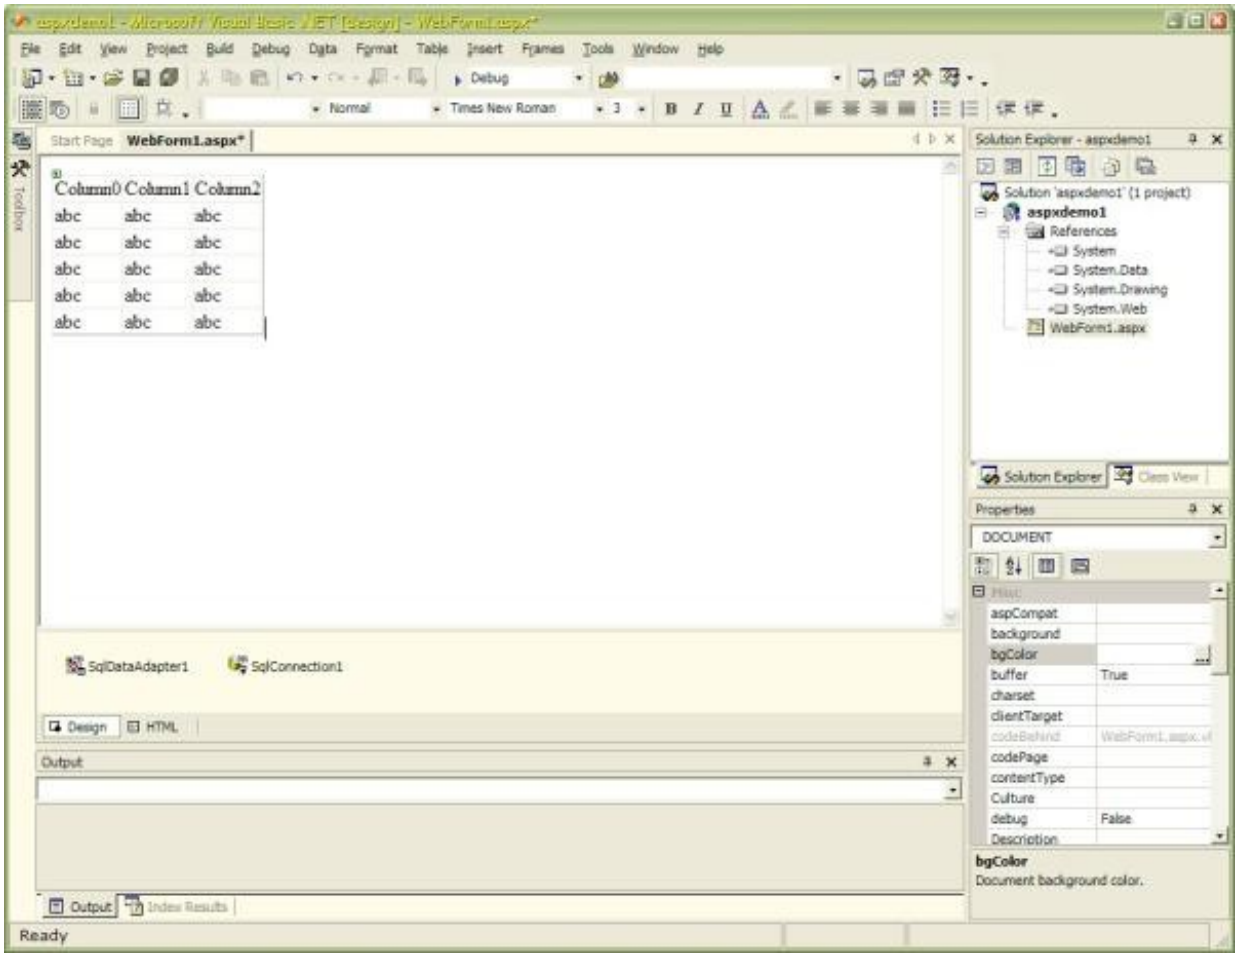
13. **Add a DataGrid Control.** Now we need to show the dataset that we are fetching from the database. We will use a simple DataGrid for this. Open the toolbox in the Web Forms panel and double-click on the DataGrid control. This add the control to the page and will display a table on the web page view.

Figure 14.30. Databound Examples using MS Visual Studio



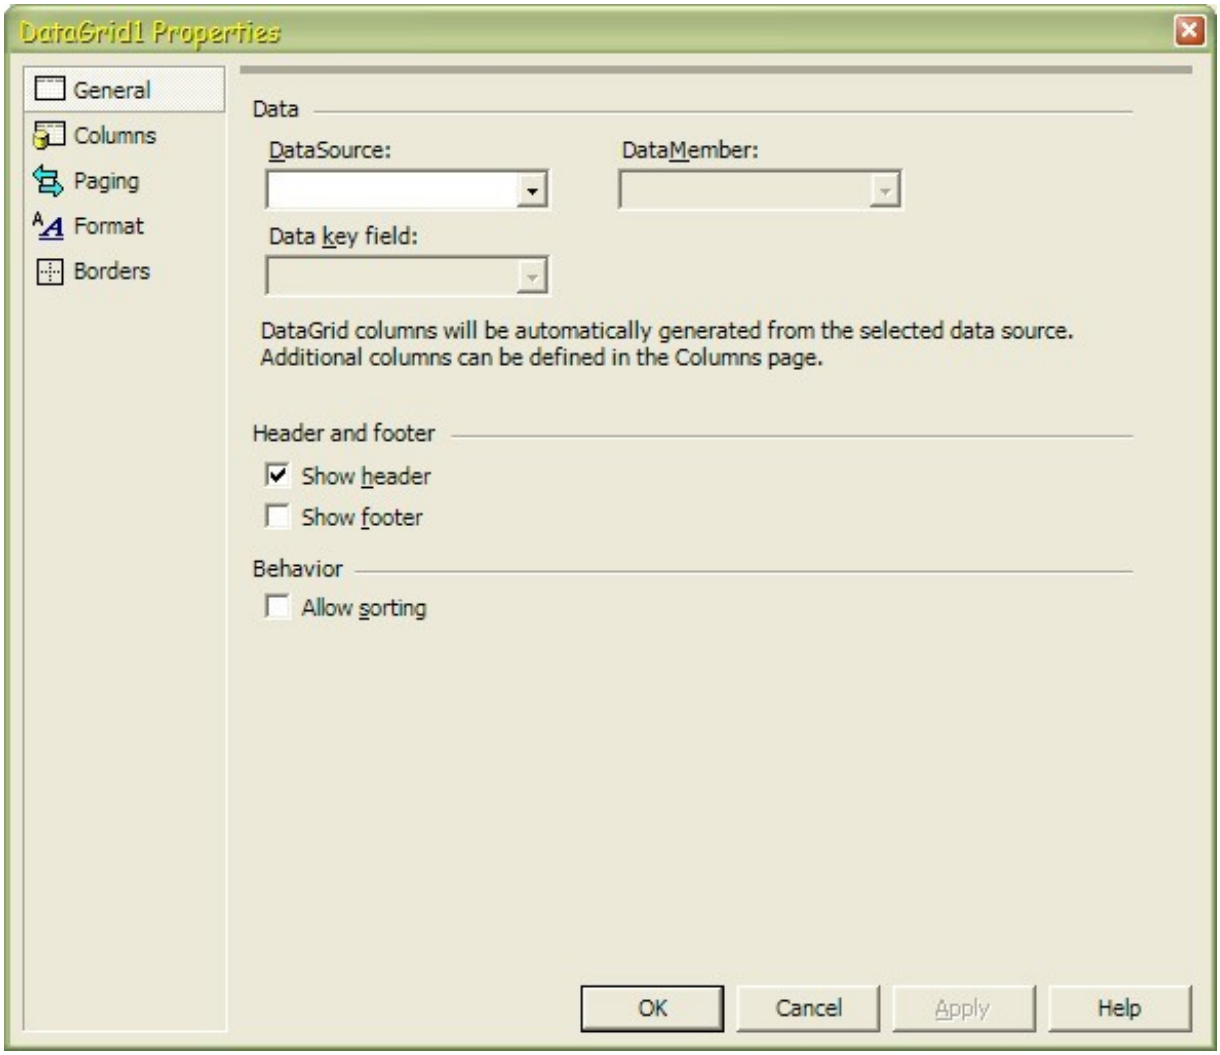
14. **Table Properties.** Configure the DataGrid control by right-clicking on the table and selecting Property Builder .

Figure 14.31. Databound Examples using MS Visual Studio



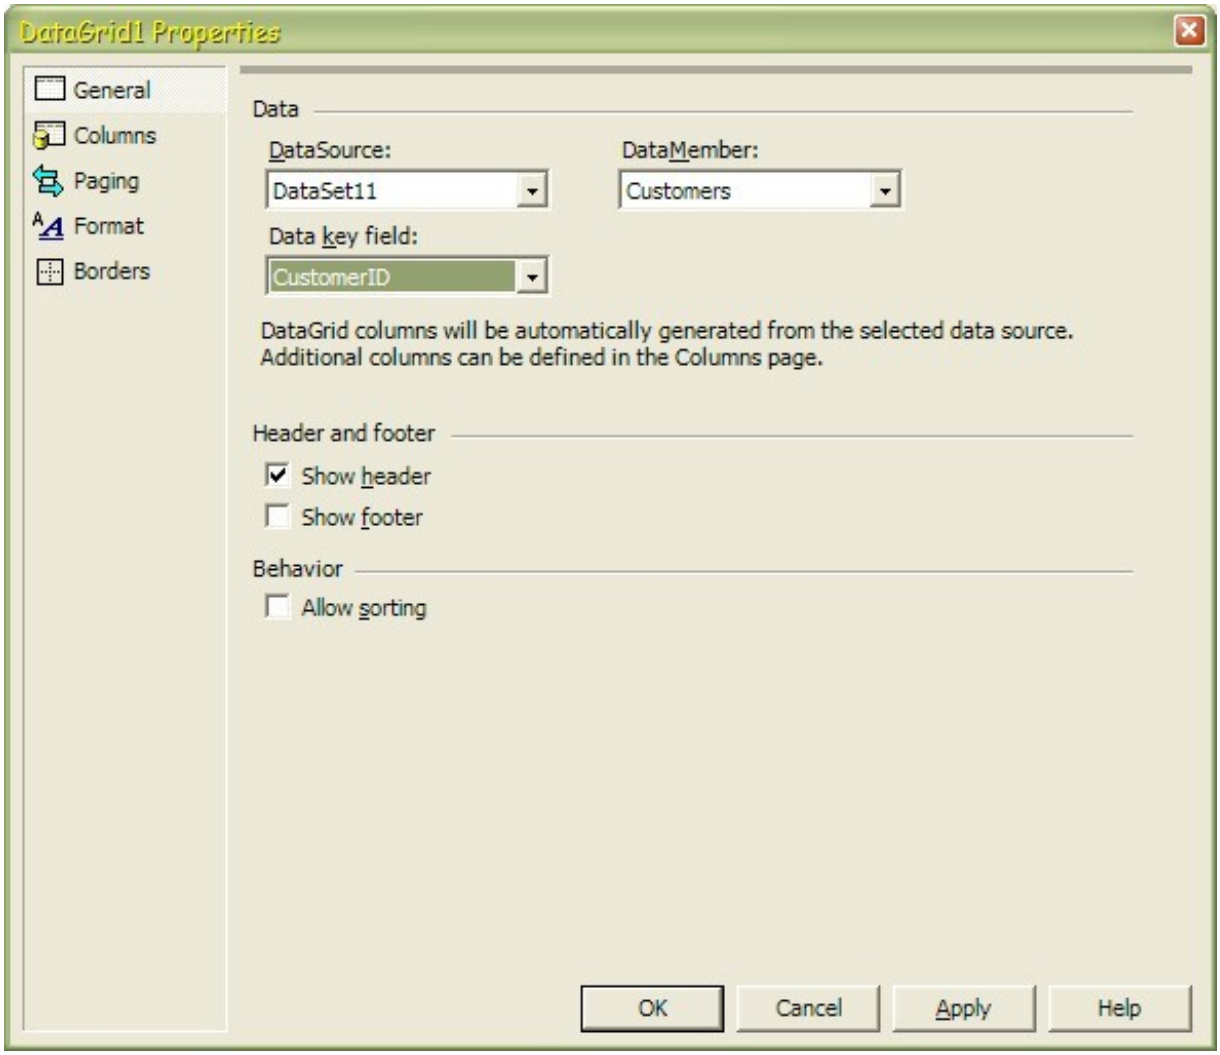
15. **DataGrid Properties.** You can adjust most properties of the table such as colours, fonts, borders, etc. You can control paging aspects that will be taken care of automatically by the control, you only need specify the number of results per page. For now we only want to adjust the most important aspects of the table, where the data comes from.

Figure 14.32. Databound Examples using MS Visual Studio



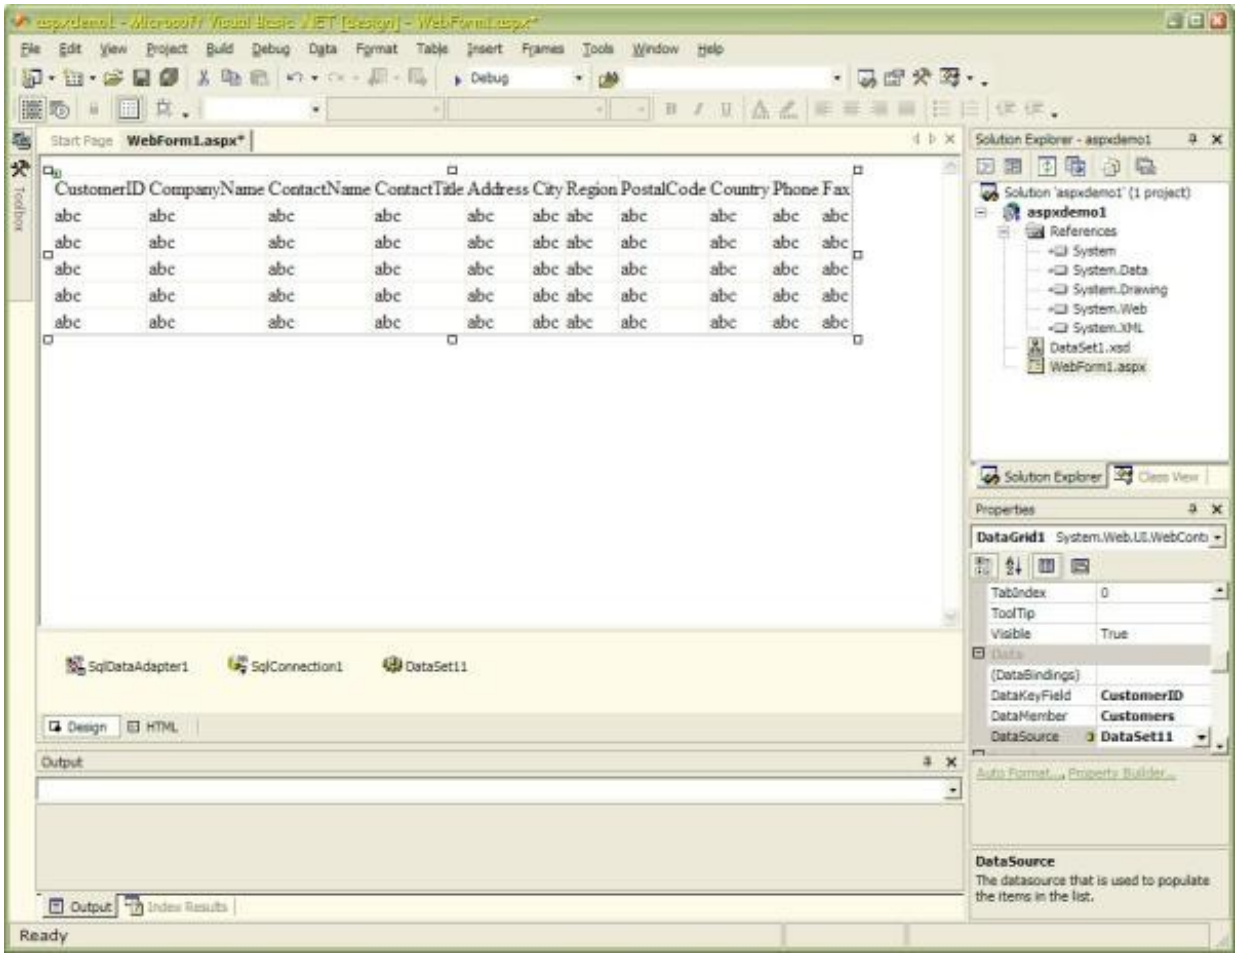
16. **DataGrid Bindings.** From the first General properties panel you must select the DataSource, DataMember, and select the Data key field (especially important for updatable tables). These properties may be selected via the drop-downs on the panel, allowing you to select the now-familiar controls configured earlier. Once configured, press the OK button to save the changes.

Figure 14.33. Databound Examples using MS Visual Studio



17. **Preview.** Once the details have been saved the view of the table in the page will be updated to reflect the dataset details.

Figure 14.34. Databound Examples using MS Visual Studio



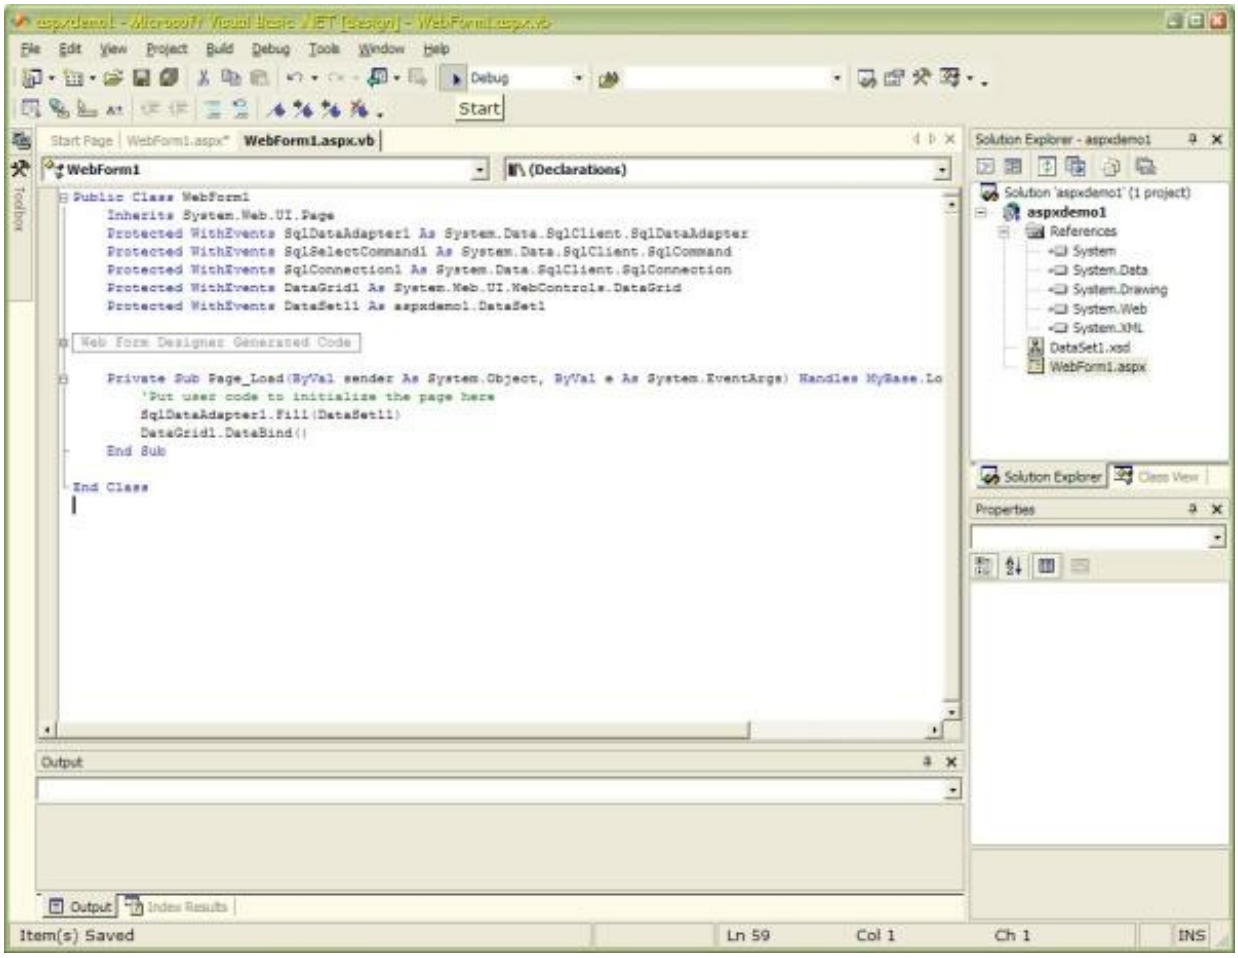
18. **Page Initialization.** We are very nearly finished. The controls are all ready to be used, however, the final touch is to edit our Page_Load function. Double-click on the empty part of the web page view in Visual Studio and the associated `.vb` file will be opened. This is the file containing the actual code. You will be automatically placed at the Page_Load function. This is the page initialization section where will need to instruct the DataAdapter to fill with data, and then instruct the DataGrid to bind to that data.

    These lines of code need to be added by hand:

    ```
    SqlDataAdapter1.Fill(DataSet11)
    DataGrid1.DataBind()
    ```

    You will find that Visual Studio will offer some assistance in the form of intellisense command-completion while you are typing.

Figure 14.35. Databound Examples using MS Visual Studio



19. **The End Result.** Next we will set the project's initial start-page by right-clicking on the form name in solution explorer and selecting Set as Start Page option. Finally we can run the project using the start button at the top. The project will automatically be built and a browser window launched automatically. Admire your results. When finished, on closing the browser windows you will automatically return to Visual Studio.

Figure 14.36. Databound Examples using MS Visual Studio

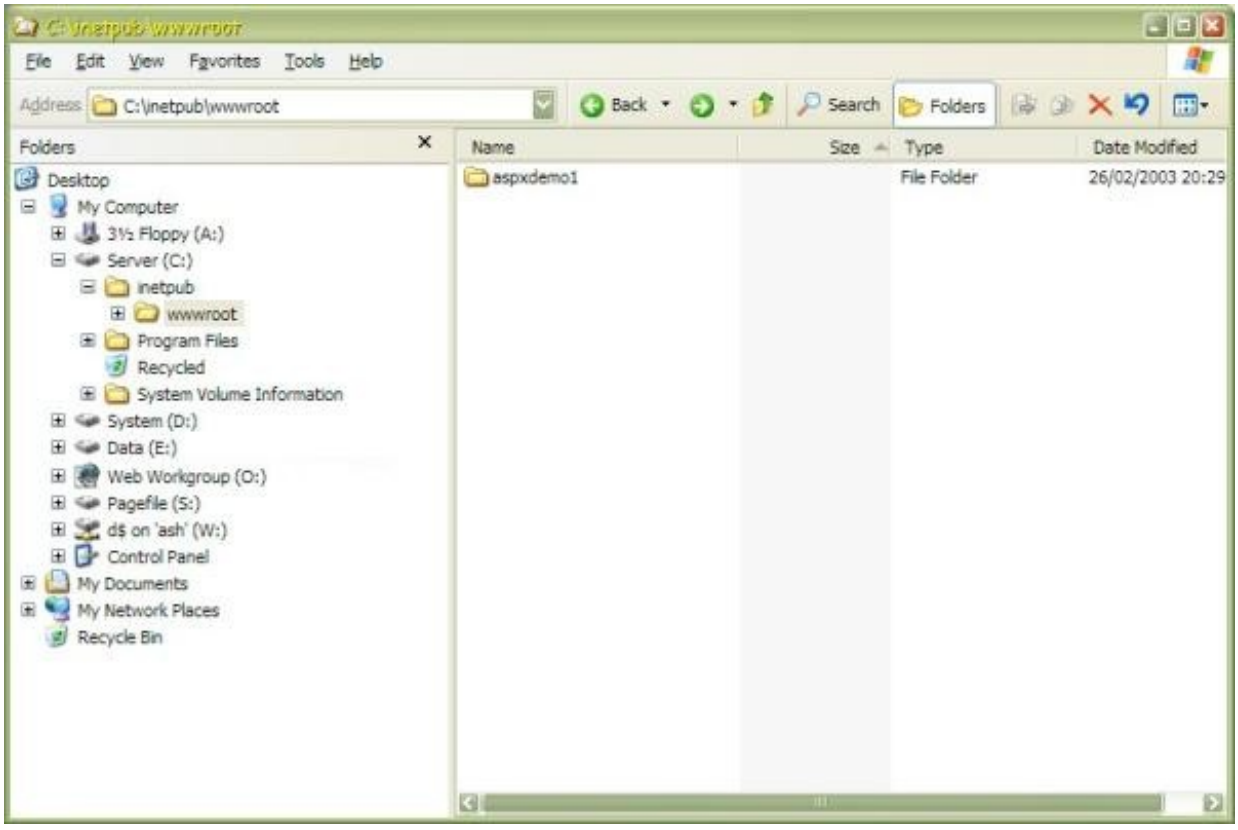
Migrating ASP.Net Applications to Virtuoso

The previous section showed us how to build a very basic web application using an ASPX data-bound control. Now we will host this same application in Virtuoso demonstrating that IIS is no longer required for ASPX application deployment.

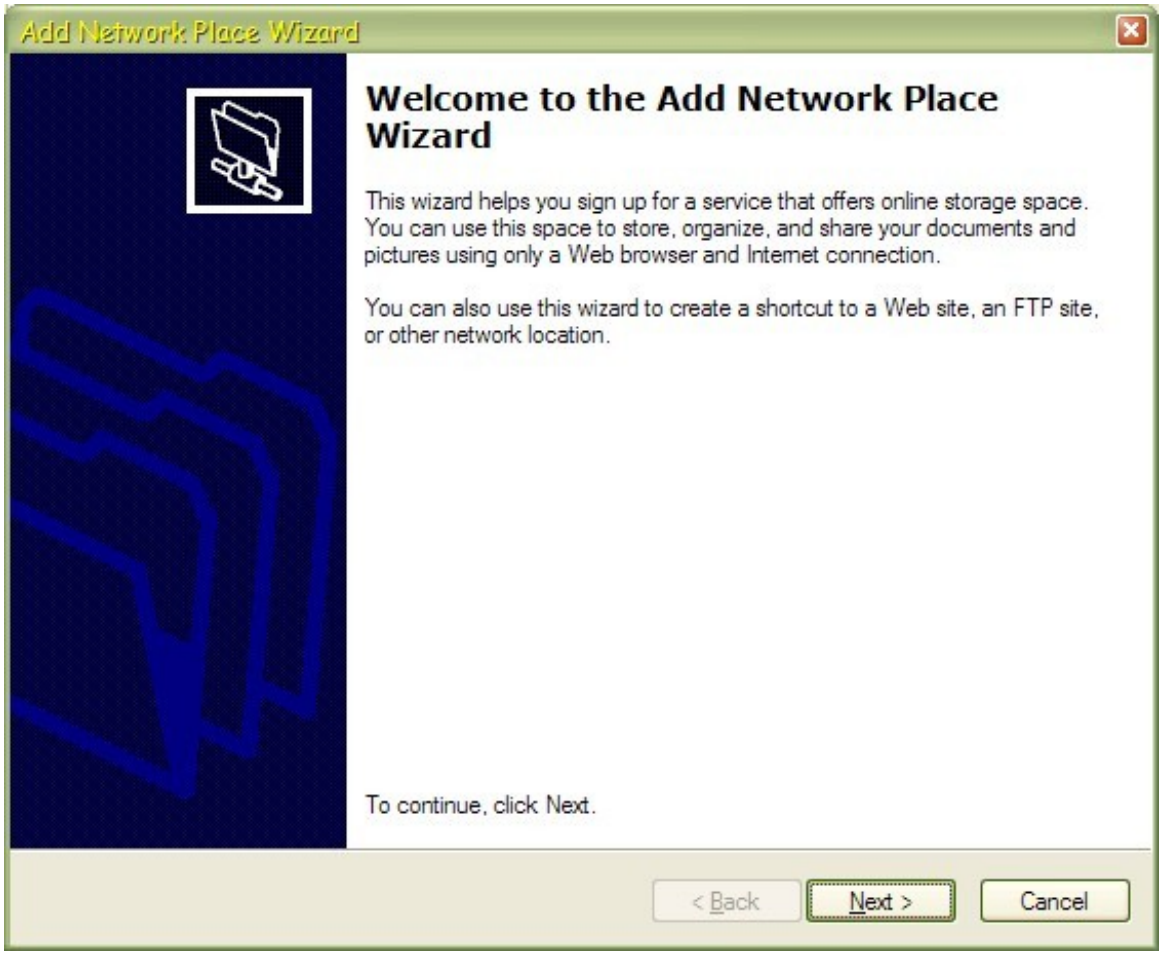
1. **Locating your ASPX application.** Use explorer to locate the ASPX application you want to move away from IIS and re-deploy under Virtuoso. The previous section created the application in the IIS virtual directory represented by `http://ash:8888/aspxdemo1/` which was physically located in `c:\inetpub\wwwroot\aspxdemo1\`. We can simply copy this directory and place it somewhere under either the VSP root directory or WebDAV. We will copy the application to a location in WebDAV for a local Virtuoso server.

Figure 14.37. Migrating ASP.Net Applications to Virtuoso



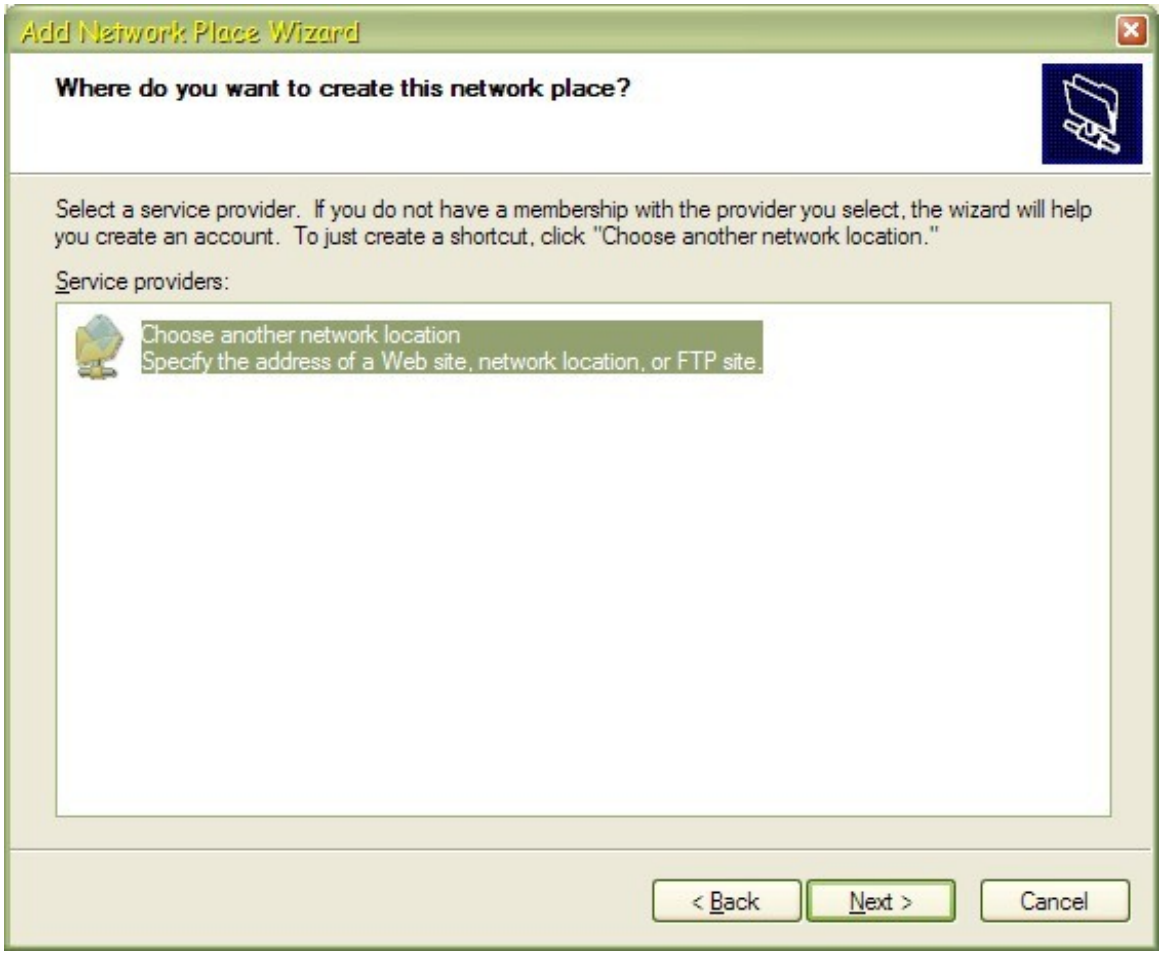
2. **Add a Network Place to DAV.** From My Network Places in explorer or Network Neighborhood double-click on the Add Network Place shortcut to start the wizard.

Figure 14.38. Migrating ASP.Net Applications to Virtuoso



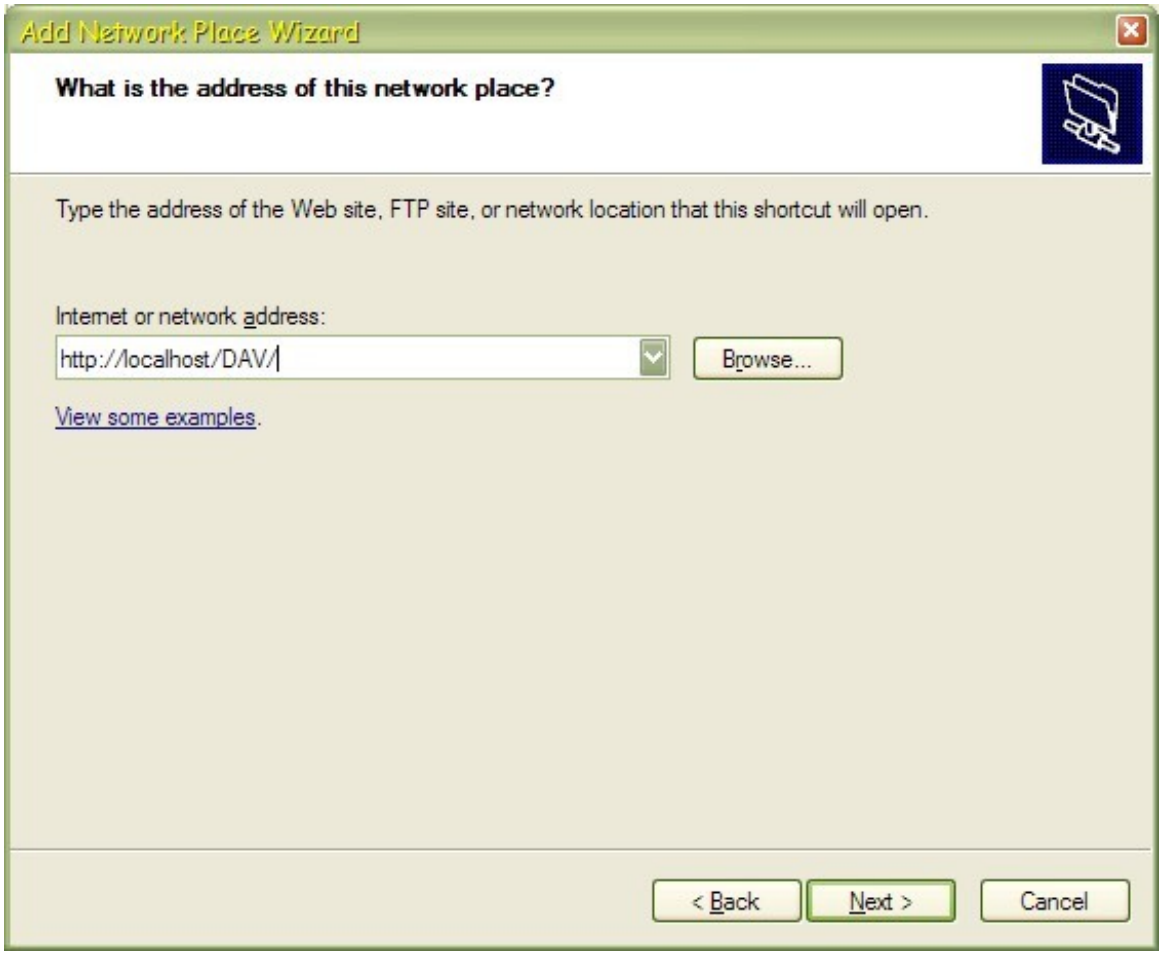
3. **Network service provider.** Select the default option. Click next to continue.

Figure 14.39. Migrating ASP.Net Applications to Virtuoso



4. **Internet or Network Address.** Here you specify the URL of DAV on the Virtuoso server. We are using Virtuoso on the local machine but this could be anywhere on the Internet. Click next to continue.

Figure 14.40. Migrating ASP.Net Applications to Virtuoso

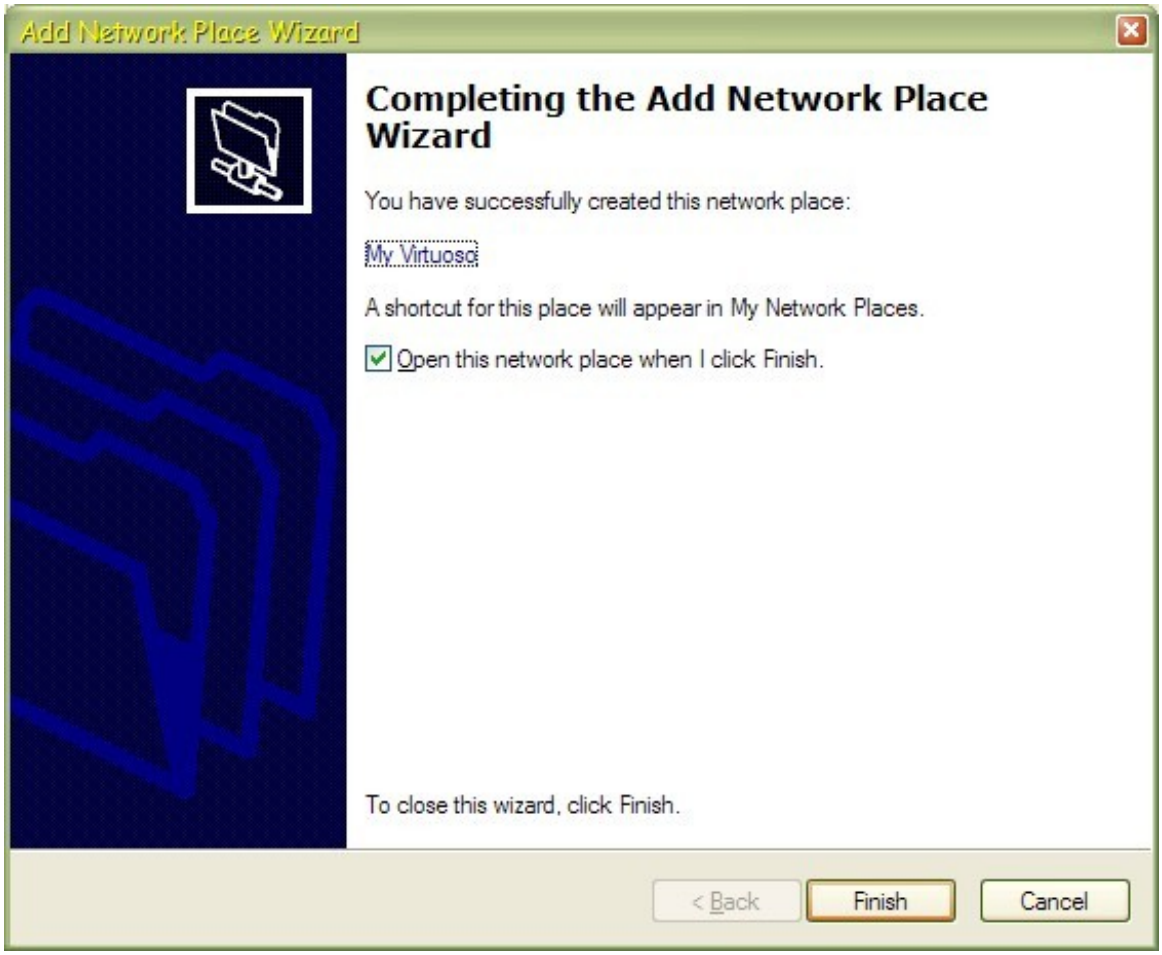


5. **Name the Network Place.** Provide the network place with a meaningful name so we can easily find this location in the future. Click on next to continue.

Figure 14.41. Migrating ASP.Net Applications to Virtuoso

6. **Open the Network Place.** On the final panel of the wizard there is a checkbox to "Open this network place when I click Finish" that we will leave checked. Click Finish to continue and open the DAV directory.

Figure 14.42. Migrating ASP.Net Applications to Virtuoso

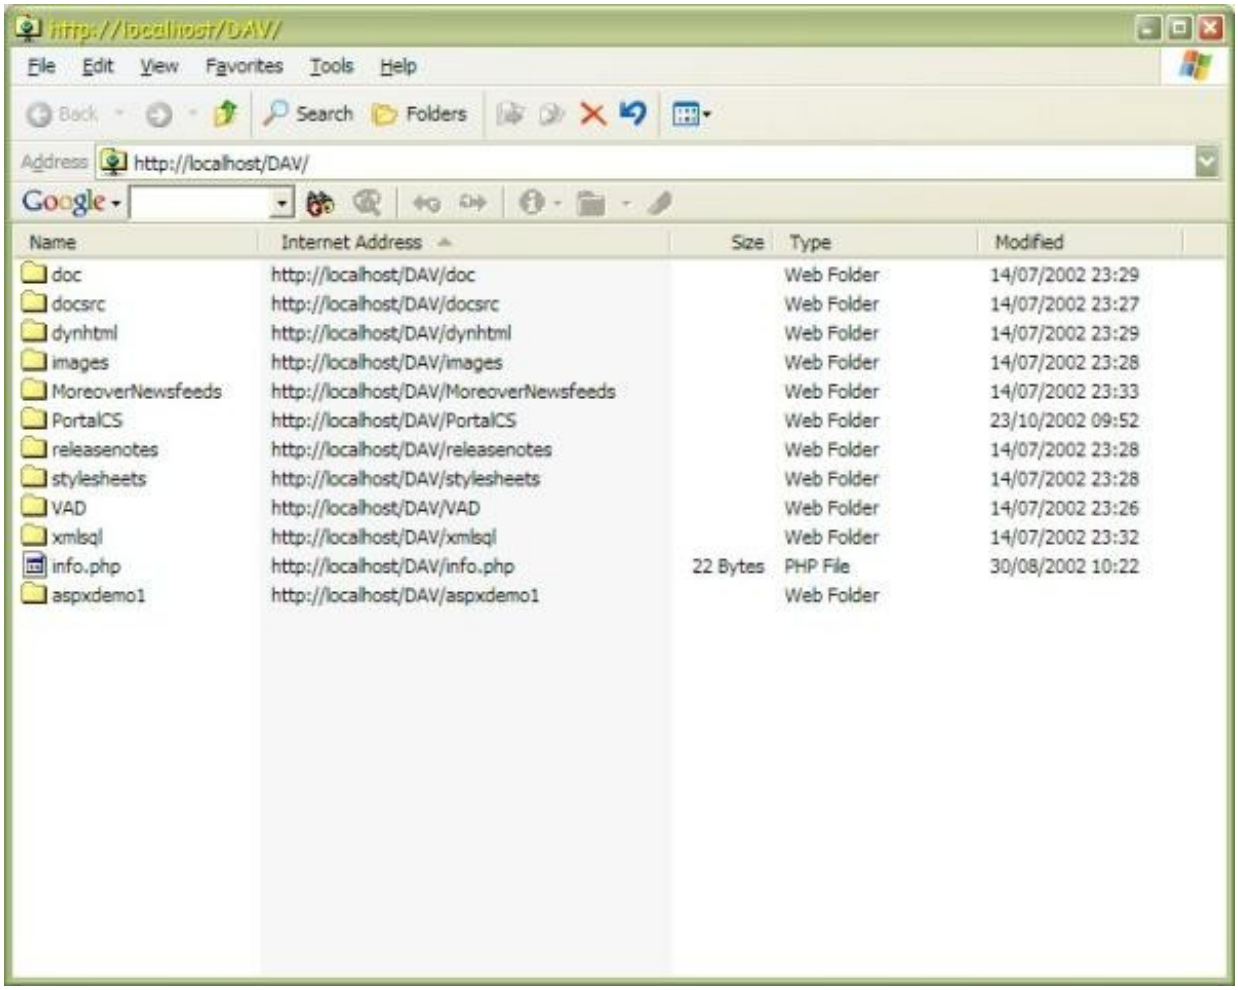


7. **Connect to DAV.** When you attempt to connect to DAV you will be prompted for a User name and Password. These will be whatever you entered during the installation, possibly both dav, in which case type dav in both fields and press the OK button to continue.

Figure 14.43. Migrating ASP.Net Applications to Virtuoso

8. **Copy the ASPX application to DAV.** Once the explorer opens up on the DAV network place we can copy the `aspxdemo1` application directory to it.

Figure 14.44. Migrating ASP.Net Applications to Virtuoso

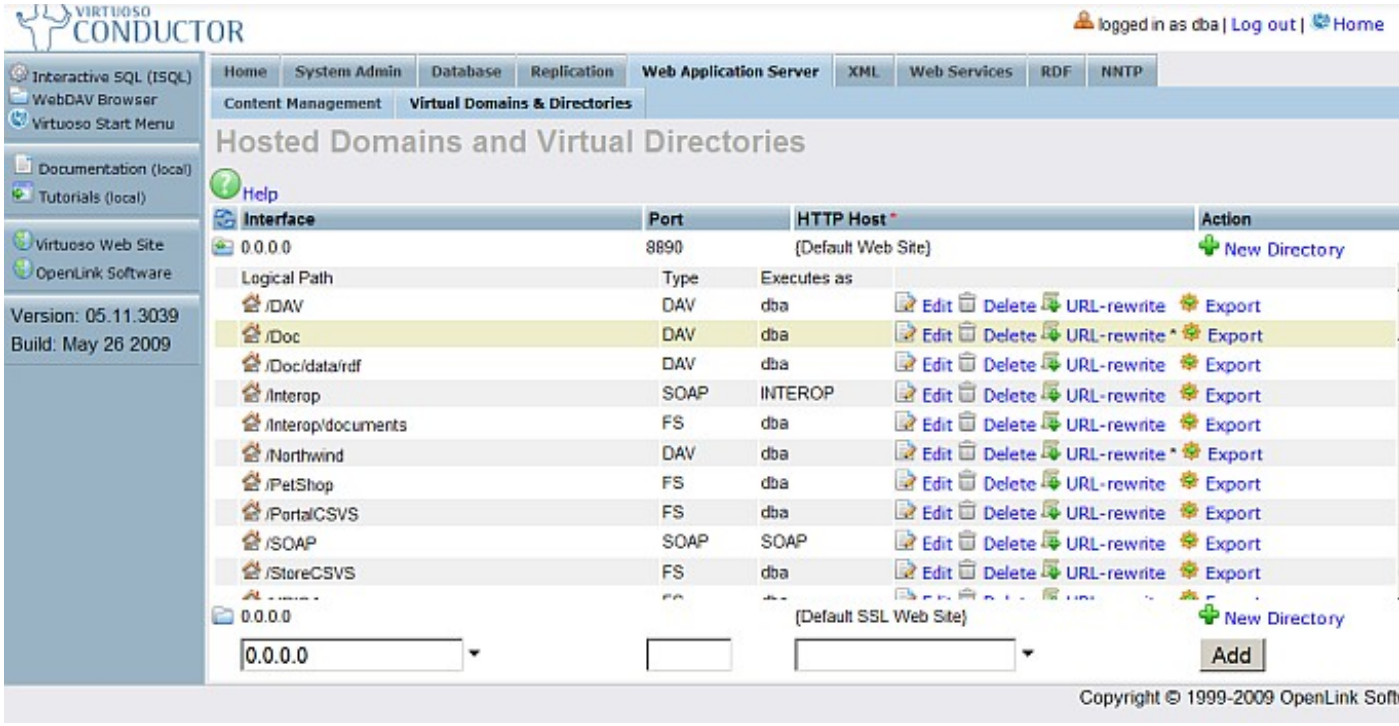


9. **Configure Virtual Directory.** Now we have to configure a Virtuoso virtual directory. Go to Conductor / Web Application Server / HTTP Hosts & Directories.

Figure 14.45. Migrating ASP.Net Applications to Virtuoso

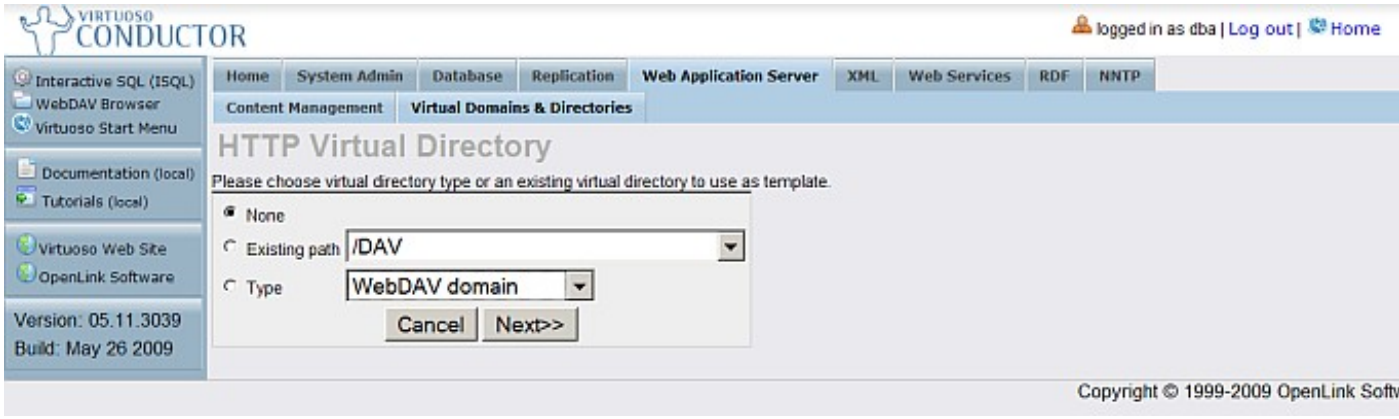
10. **Add Virtual Directory.** The "folder" icon for the hosts defined will list all mappings currently present for the Virtuoso server. Click on the "New Directory" link to continue.

Figure 14.46. Migrating ASP.Net Applications to Virtuoso



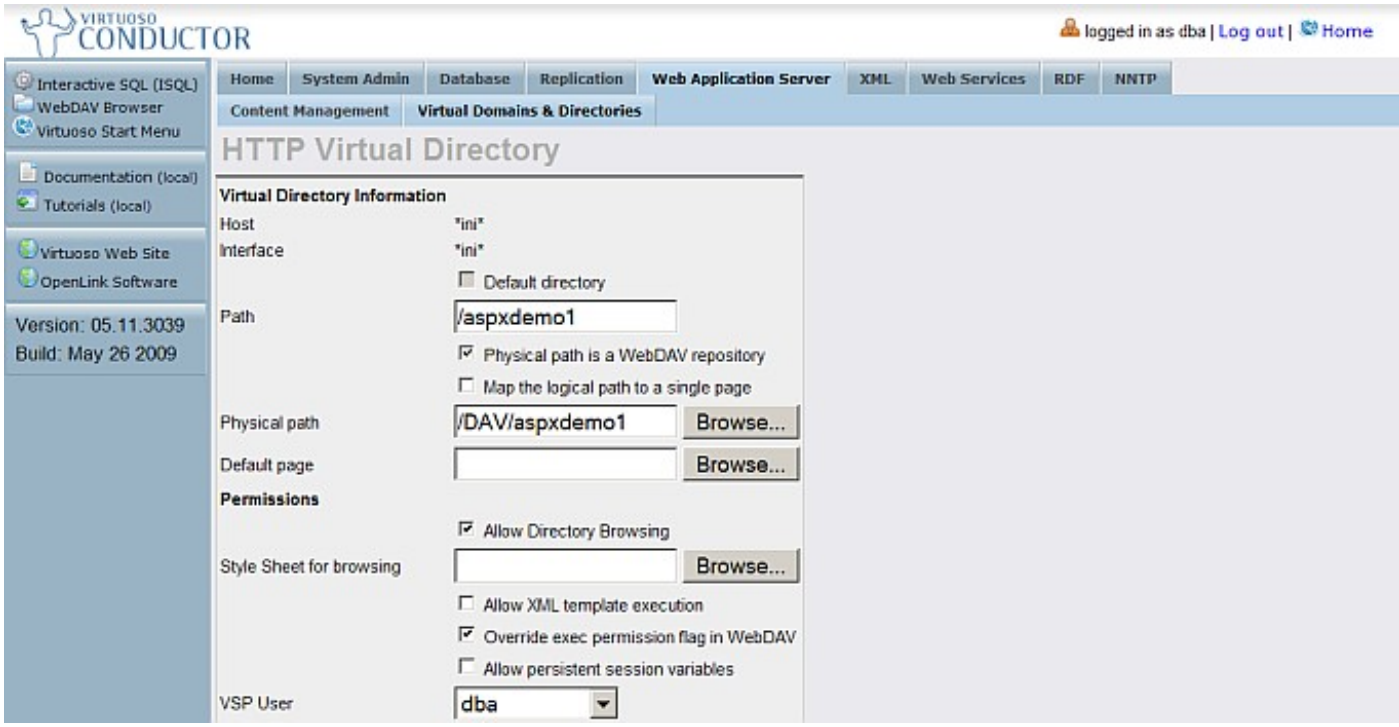
11. **Select DAV Domain template.** On the next page select for "Type" the DAV Domain template and click "Next".

Figure 14.47. Migrating ASP.Net Applications to Virtuoso



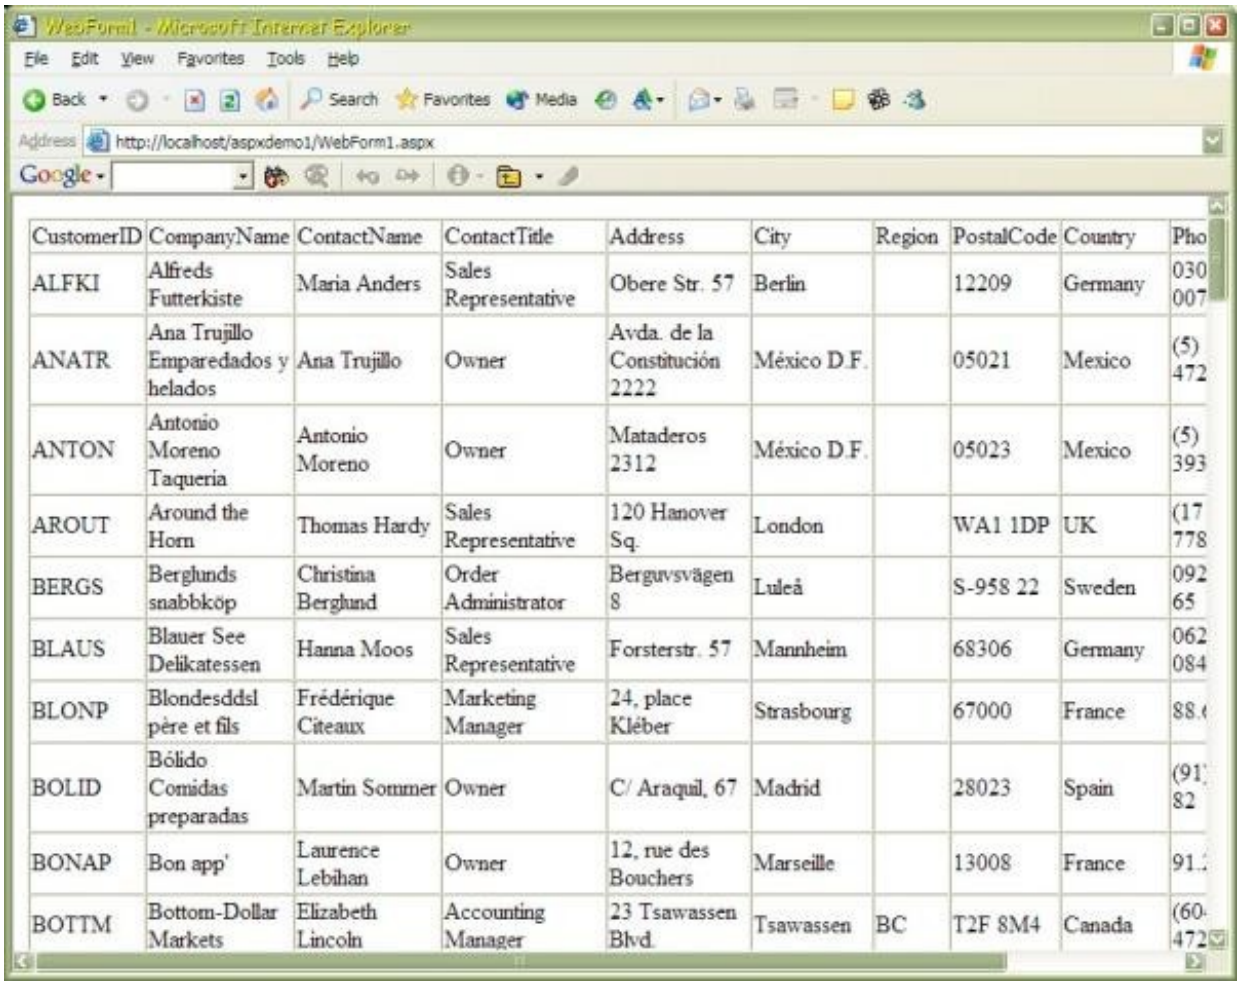
12. **Configure the Virtual Directory parameters.** We must supply a logical path, `/aspxdemo1` , in this case. We must also supply the physical path that this represents, we can either type in the DAV location or use the Browse button to the find the directory under DAV. The WebDAV checkbox will correctly already be checked. For now we will also set to Allow Directory Browsing, and Override execution permissions in WebDAV. Finally we must set the VSP Execution user to `dba` using the drop down. To save the changes click on the "Save Changes" button at the bottom of the page.

Figure 14.48. Migrating ASP.Net Applications to Virtuoso



13. **View the ASPX page hosted in Virtuoso DAV.** With the virtual directory configured we have only to test that it works as expected. On opening a browser at: `http://example.com/aspxdemo1/WebForm1.aspx`, we will see the same output as before.

Figure 14.49. Migrating ASP.Net Applications to Virtuoso



Note:
If ASPX hosting is attempted on a machine that never had IIS installed it is possible that ASP.NET is not configured, although required. The Virtuoso installer will take care of this for you in most cases but if you run into problems you may want to confirm that ASP.NET is configured correctly. You will have to use the regedit utility to edit the registry, changing a search-path so System.Web.dll can find aspnet_asapi.dll. Always exercise caution whenever editing the registry as invalid data can prevent your machine from operating properly.

You will first need to find out what version of the `aspnet_isapi.dll` library you have. The simplest way to determine this is by locating the file and right-clicking properties on it from explorer.

Assuming the version is 1.0.3705.288, we should enter the following details into the registry if the `HKLM\Microsoft\ASP.NET` key is missing (if your version differs change it accordingly):

```
[HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\ASP.NET]
     "RootVer"="1.0.3705.288"
[HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\ASP.NET\1.0.3705.288]
     "Path"="C:\WINDOWS\Microsoft.NET\Framework\v1.0.3705"
     "DllFullPath"="C:\WINDOWS\Microsoft.NET\Framework\v1.0.3705\aspnet_isapi.dll"
```

14.6. ASMX Web Service Hosting

Microsoft ASMX Web Services can be hosted in exactly the same way as ASPX Applications can be. A ASMX Web Services Project created in Visual Studio can be copied to either the file system (under the VSPROOT directory) or the Virtuoso WebDAV repository. You must copy the project directory to the required location and then make a Virtual Directory pointing to it. If the location is in WebDAV then ensure that execute permissions are set for any .asmx files.

ASP.Net Web Application Hosting

14.7. Blogging & Weblogs

Weblogs, or Blog, are web pages or sites organized by date. The content of a typical blog page contains short messages listed in chronological order. The blog messages are typically excerpts of HTML markup, since they typically appear on web sites and expect web browsers as clients.

In the rest of this document we will use interchangeable the terms "blog" and "weblog", and refer to the users that have a blog as "bloggers".

The following terms are also commonly used in this section:

RSS/OCS/OPML/RDF/Atom - file formats, XML based to represent data or list of files containing a data

Channels - a public source containing data in any of XML/text/HTML format, usually in RSS format.

Post/Article(message) - this is a piece of information describing something in a human readable format, in some language. This can be have satellite parts as title, excerpt, publication data etc.

PermaLink - a URL that uniquely designates a single article in blog-space and time.

The Virtuoso Blog system comprises a native Web-based interface for publishing and blog administration, but can also be interacted with using an XML-RPC API. The Virtuoso server supports the following XML-RPC APIs for blogging purposes:

Blogger API

MetaWeblog API

Movable Type

In addition to the blogger APIs Virtuoso supports:

xmlStorageSystem - this allows blogging clients to upload static (ready to go) content onto a Weblog server.

Weblogs ping API - to allow cross-server notification for the latest updated sites/blogs

Pingback and Trackback API - to allow bloggers to notify each other.

Subscription Harmonizer - to allow bloggers to keep their subscriptions in-sync.

14.7.1. The Virtuoso Blogging Application

Blogs provide their authors with a location on the Internet or Intranet to receive their thoughts, experiences, idea, or simply anything they have a desire to write about. For this most part, audience is neither expected nor required, however comments and feedback are common place.

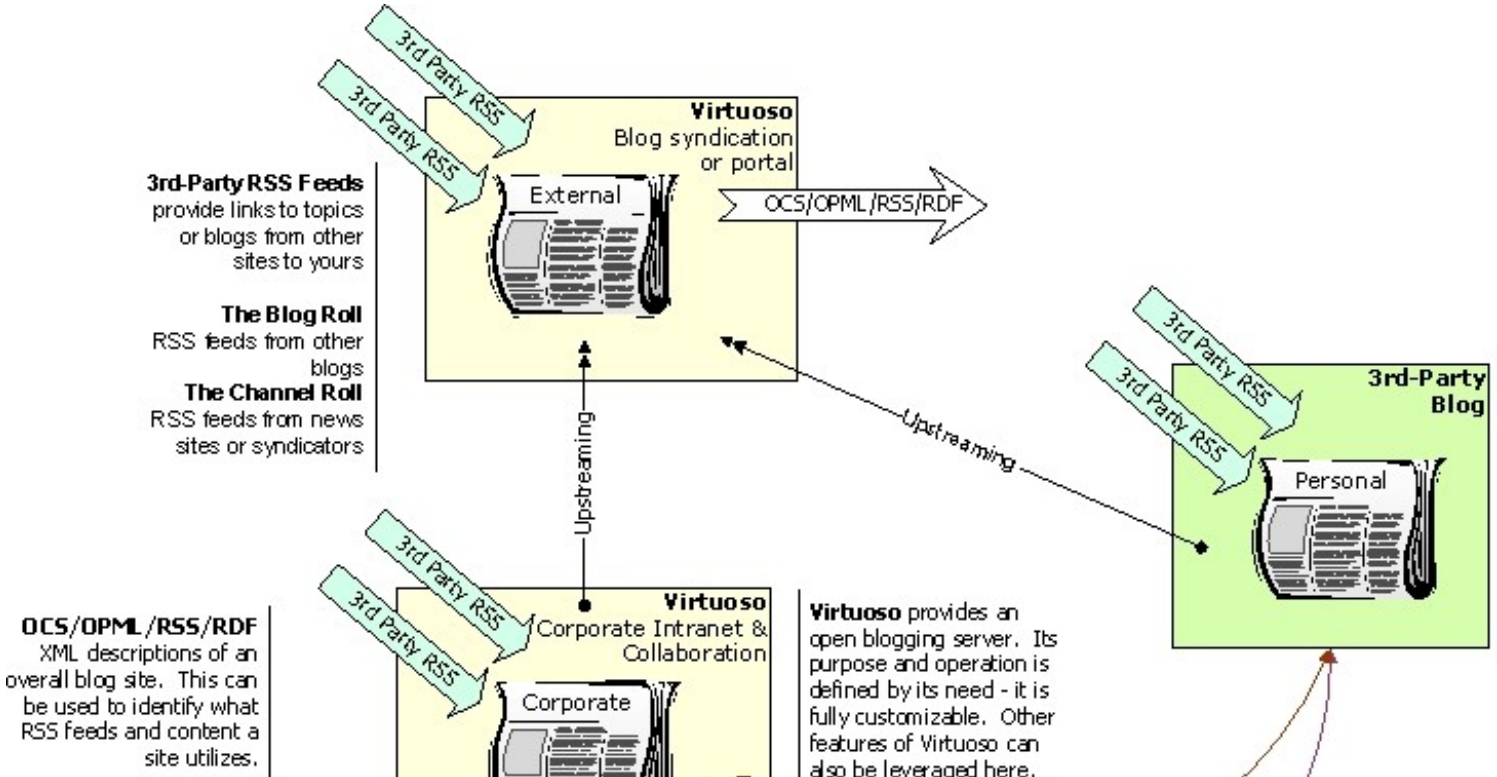
Blogs originated as a form of public diary. Their exploitation has seen them as a useful tool for finding personal reviews to products, situations or general news as guidance for their readers. These can be viewed quicker and more informative than regular journalism.

Corporate blogs, or use of blogging can be a valuable source of company information propagation. Members of the company can blog about the activities or findings with no particular audience in mind. This provides a continual journal or account of the company's undertakings that is really self-documenting for every other employee how they fit into the overall picture. Over time a searchable knowledge base will unravel itself, people may need information about a product or some aspect of internal support that took place possibly years prior, otherwise forgotten, stored within the blog.

Virtuoso implements the three major APIs for blogging which makes instantly attractive to any standard blog application. Virtuoso provides blog authoring applications of its own. On a personal level, your blogs can be stored or exposed using the most appropriate server, authored using the most appealing client and everything held in right places by Virtuoso. On a community level you get the same but scaled upwards for each member individually, and further more, centrally. Virtuoso can generate and automatically maintain a blog site specially for blog collaboration within a community suitable for a corporate need. All members are listed on the front page and have the opportunity to contribute (publish) to the main blog view. All blogs are fully free text searchable - a simple exploit of the Virtuoso free-text engine.

Virtuoso can provide the blog client, server or relay for blogs or any RSS or XML-feed based channel or information.

Figure 14.50. Virtuoso Blogging Conceptual Diagram



Syndication to your Blog - RSS & RDF

The default Virtuoso blog implementation maintains a "blog/gems" subdirectory for each blog account. Within this is an RDF file and an RSS file. These provide direct access to the blog information in XML. Other bloggers or news syndicators can read just the site contents, apart from the web interface that Virtuoso provides, potentially applying an XSLT transformations suitable to their application or circumstance, for example reading the blog from a PDA or mobile device.

Rich Site Summary (RSS) is a lightweight XML format designed for sharing headlines and other Web content. Think of it as a distributable "What's New" for your site. Each RSS text file contains both static information about your site, plus dynamic information about your new blog entries. Each entry is defined by an <item> tag, which contains a headline TITLE, URL, and DESCRIPTION. For example:

```
...
<item>
  <title>RSS Resources</title>
  <link>http://www.webreference.com/authoring/languages/xml/rss/</link>
  <description>Defined in XML, the Rich Site Summary (RSS) format has
  quietly become a dominant format for distributing headlines on the Web.
  Our list of links gives you the tools, tips and tutorials you need to get
  started using RSS. 0323</description>
</item>
...
```

The Resource Description Framework (RDF) integrates a variety of applications from library catalogs and world-wide directories to syndication and aggregation of news, software, and content to personal collections of music, photos, and events using XML as an interchange syntax. The RDF specifications provide a lightweight ontology system to support the exchange of knowledge on the Web.

Channels - OCS & OPML

The default Virtuoso blog implementation maintains a "blog/gems" subdirectory for each blog account. Within this are an OCS file and an OPML file. Both files provide an outline or hierarchical list of RSS feeds linked to the blog account in these two popular formats designed for channel/list exchange. The files are variably accessible following:

```
http://virtserv/DAV/myaccount/blog/gems/index.ocs
http://virtserv/DAV/myaccount/blog/gems/index.opml
```

Open Content Syndication (OCS), an application of XML, is an RDF description of all external RSS feeds linked to the blog site.

The OCS Directory format is designed to enable channel listings to be constructed for use by portal sites, client based headline software and other similar applications.

Outline Processor Markup Language (OPML) is a very simple XML format for storing information in outline format. XML being inherently hierarchical, OPML constrains XML so that a wide variety of applications can build in OPML support with the comfort of knowing it will work with any other OPML tool. Type of information stored in such hierarchies are web browser bookmarks, web directories, collaborative outlines, song playlists, and even web-site content, OPML is a great balance between the wide open freedom of raw XML and the feeling of security of a formal vocabulary.

The OCS RDF file is an XML of nested <rdf:descriptions> tags loosely defined as follows:

```
<rdf:RDF>
  <rdf:description>
      This contains a description of this RDF originator
    <rdf:description>
        Description of a link RSS blog or news feed
       <rdf:description>
         Description of the URL containing the above described
         RSS feed and details about its format, update frequency
         and when the link for established.
       </rdf:description>
    </rdf:description>
      more RSS descriptions may follow, one for each
      linked.
  </rdf:description>
</rdf:RDF>
```

Here is an example of the contents of the index.ocs file describing a single linked RSS news feed.

```
<rdf:RDF
    xmlns:rdf="http://www.w3.org/1999/02/22-rdf-syntax-ns#"
    xmlns:ocs="http://InternetAlchemy.org/ocs/directory#"
    xmlns:dc="http://purl.org/metadata/dublin_core#">
  <rdf:description about="">
  <dc:title>My Blog</dc:title>
  <dc:creator>blog@openlinksw.com</dc:creator>
  <dc:description />
  <rdf:description about="http://msdn.microsoft.com/">
    <dc:title>MSDN Just Published</dc:title>
    <dc:creator />
    <dc:description />
    <dc:subject />
    <dc:image />
    <rdf:description about="http://msdn.microsoft.com/rss.xml">
      <dc:language>us-en</dc:language>
      <ocs:format />
      <ocs:updatePeriod>hourly</ocs:updatePeriod>
      <ocs:updateFrequency>1</ocs:updateFrequency>
      <ocs:updateBase>1999-05-30T00:00</ocs:updateBase>
    </rdf:description>
  </rdf:description>
</rdf:RDF>
```

The OPML file is more simple, the corresponding index.opml would be as follows:

```
<opml>
  <body>
```

```
      <outline
        title="MSDN Just Published"
        htmlUrl="http://msdn.microsoft.com/"
        xmlUrl="http://msdn.microsoft.com/rss.xml" />
      more outline tags for each description...
    </body>
  </opml>
```

Personal Blog Sites

Every WebDAV account with a home directory has the option to create a default personal blog site. The default blog pages contains a call to a function that produces XML data containing a list of messages, calendar for archive navigation and channels that the owner has subscribed to. This blog directory and pages are generated upon initial sign-in of the user. Each WebDAV account with a blog directory will thus have the following:

```
http://<host:port>/DAV/<uname>/blog/
```

containing the following:

index.vspx - The default blog home page using VSPX controls.

gems/rss.xml - The RSS v2.0 file presenting the user's blog data.

gems/rss92.xml - The RSS v0.92 file presenting the user's blog data.

gems/rss91.xml - The RSS v0.91 file presenting the user's blog data.

gems/index.rdf - the user's blog data in RDF format.

gems/index.ocs - the user's channels represented in OCS format.

gems/rsd.xml - Really Simple Discovery file for the blog. This helps client software to find the services needed to read, edit, post etc.

gems/atom.xml - Atom feed file. It's similar to the RSS file but in different format.

gems/backlog.xml - RSS v2.0 file containing all posts in user's blog.

gems/foaf.xml - 'Friend Of Friend' file. This is to provide in a machine-processable format, about blogger, his/she interests, location, friends etc.

gems/index.opml - the user's channels represented in OPML format.

gems/ocs.xml - the user's channels represented in OCS format.

gems/opml.xml - the user's channels represented in OPML format.

comments.vsp - a VSP page for posting a comment to the user's blog.

default.xsl - an XSL-T style sheet providing the default HTML view of the blog XML data.

comments.vsp - pop-up for blog comments (obsoleted)

default.css - CSS for pages

main.xsl - VSPX controls for index.vspx

calendar.xsl - calendar control

trackback.xsl - pop-up for trackbacks (obsoleted)

rss_feeds/ - folder containing channel RSS feeds in XML format

The `rss.xml` , `index.rdf` , `index.ocs` files are dynamic SQL-XML resources, they are not static files and must not be deleted. Their content is generated in real-time per request.

Blog users may edit the `default.xsl` in order to change the appearance of the default page of their Blog.

Example 14.52. Default blog home (index.vspx) page

The following is source of default blog home page. It's built using a VSPX and macro expansion. All page components are represented with <vm:* /> this makes page more simpler and allows users to change it's appearance using custom VSPX components.

```
<v:page xmlns:vm="http://example.com/vspx/weblog/"
  xmlns:v="http://example.com/vspx/"
  style="main.xsl" name="blog-home-page"
  doctype="-//W3C//DTD XHTML 1.0 Transitional//EN"
  doctype-system="http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
```

```
  <vm:page
xml:id="<uid>">
    <vm:header>
      <vm:title/>
      <vm:disco-rss-link/>
      <vm:disco-pingback-link/>
      <vm:meta-author/>
      <vm:meta-description/>
      <vm:meta-keywords/>
      <vm:style url="default.css" />
    </vm:header>
    <vm:body>
      <div
xml:id="header">
        <img src="/blog/blogs/images/bloglogo.jpg" alt="OpenLink Virtuoso Blog"/>
        <h1><vm:blog-title/></h1>
        <h2><vm:blog-about/></h2>
      </div>
      <div
xml:id="navbartop">
        <div>Entries: [ <vm:entry-list /> ]</div>
      </div>
      <table
xml:id="pagecontainer" cellspacing="10" cellpadding="0" border="0" width="100%">
        <tr>
          <td class="box">
             <div class="box">
                  <div class="roll" style="border: none; border">
                    <div align="center" style="margin-bottom: 3px;">
                      <b>Personal Details</b>
                    </div>
                    <div style="margin-bottom: 3px;"><vm:site-home>Home</vm:site-home></div>
                    <vm:if test="contact">

```

```
</v:page>
```

Example 14.53. Blog home (index.vsp) page

The XML Schema representing the XML data for blog home page is represented below. Following this fragment is the `default.xsl` XSL style sheet that would be used to transform XML document valid to this into the default web page for public consumption on the Internet or Intranet.

```
<?xml version="1.0" encoding="UTF-8"?>
<xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema">
  <xs:element name="about">
    <xs:complexType/>
  </xs:element>
  <xs:element name="blog">
    <xs:complexType mixed="true">
      <xs:choice minOccurs="0" maxOccurs="unbounded">
        <xs:element ref="title"/>
        <xs:element ref="about"/>
        <xs:element ref="email"/>
        <xs:element ref="items"/>
        <xs:element ref="navigation"/>
        <xs:element ref="copy"/>
        <xs:element ref="disclaimer"/>
      </xs:choice>
      <xs:attribute name="base" type="xs:anyURI"/>
      <xs:attribute name="category" type="xs:string"/>
      <xs:attribute name="category-name" type="xs:string"/>
      <xs:attribute name="post" type="xs:string"/>
      <xs:attribute name="trackback-url" type="xs:anyURI"/>
    </xs:complexType>
  </xs:element>
  <xs:element name="blogroll">
    <xs:complexType>
      <xs:sequence>
        <xs:element ref="link"/>
      </xs:sequence>
      <xs:attribute name="id" type="xs:boolean" use="required"/>

      <xs:attribute name="href" type="xs:anyURI" use="required"/>
      <xs:attribute name="rss" type="xs:anyURI" use="required"/>
    </xs:complexType>
  </xs:element>
  <xs:element name="message">
    <xs:complexType>
      <xs:sequence>
        <xs:element ref="id"/>
        <xs:element ref="title"/>
      </xs:sequence>
    </xs:complexType>
  </xs:element>
  <xs:element name="navigation">
    <xs:complexType>
      <xs:sequence>
        <xs:element ref="calendar"/>
        <xs:element ref="blogroll"/>
        <xs:element ref="categories"/>
      </xs:sequence>
    </xs:complexType>
  </xs:element>
  <xs:element name="pubDate" type="xs:string"/>
```

```
  <xs:element name="title">
    <xs:complexType>
      <xs:simpleContent>
        <xs:extension base="xs:string">
          <xs:attribute name="blogid" type="xs:byte"/>
        </xs:extension>
      </xs:simpleContent>
    </xs:complexType>
  </xs:element>
  <xs:element name="trackbacks" type="xs:boolean"/>
  <xs:element name="week">
    <xs:complexType>
      <xs:sequence>
        <xs:element ref="day" maxOccurs="unbounded"/>
      </xs:sequence>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

The XML data as following XML Schema above will be transformed using the following XSL-T style sheet, default.xsl:

```
<?xml version="1.0"?>

<xsl:stylesheet
    xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
  version="1.0"
    xmlns:vb="http://example.com/weblog/"
    xmlns:vtb="http://example.com/weblog/tb/" >

  <xsl:output method="xml" doctype-public="-//W3C//DTD XHTML 1.0 Transitional//EN"
    doctype-system="http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd"
        indent="yes" encoding="UTF-8" omit-xml-declaration="yes" media-type="text/html"/>

  <xsl:template match="/">
    <html>
      <head>

    <xs:element name="url" type="xs:anyURI"/>
    <xs:element name="webMaster" type="xs:string"/>
    <xs:element name="width" type="xs:int"/>
  </xs:schema>
```

14.7.2. Blogger Clients Compatibility

The Virtuoso Blog server implementation has been tested against the following blog client applications:

Radio Userland (Manila Blogger Bridge tool and Upstreaming), available for MS Windows and MacOS X

NewzCrawler , available for MS Windows

w.bloggar , available for MS Windows

blogBuddy , available for MS Windows

Zempt , available for MS Windows

BlogMan , available for MS Windows

thinblog , Java based client

The steps required to allow third-party clients to operate with Virtuoso are:

1. Create a WebDAV account using the Server Administration Interface making sure that the home directory is created as /DAV/<username>/
2. Enable the XML-RPC bridge on a SOAP endpoint (see "XML-RPC endpoint configuration" section above)
3. Most client tools accept a username and password, enter the credentials and URI for XML-RPC endpoint.
4. Allow the client tool time to refresh the Blog data.
5. Post a simple message, verify its creating using the Server Administration Interface's Weblog link.

Interoperability Notes. The "Zempt" application will report an error upon startup saying that "mt.supportedTextFilters" are not supported, however it it will continue to work with the Virtuoso's blogging server.

14.7.3. Blogs Management User Interface

The Server Administration Interface provides a way to manage existing blogs. The Blog user interface is accessible from the Web Services >> Weblogs menu. The page will show existing blogs on the server and will allow you to erase, edit existing, or make

new blog sites.

Blog channels and categories are also configurable from this interface.

14.7.4. Community Blog Site

The community blog site feature pools all blog efforts into one page providing a blog community portal. No personal blogs are altered, the community site provides a super-set for all blogs.

The community blog site is activated by enabling blogging capabilities on the DAV administrator account "dav". This can be achieved at two places, on the Users Administration interface or the Web Services >> Weblogs interface in the Server Administration Interface menu.

14.7.5. Blogger API

The Virtuoso server supports the following methods available via XML-RPC for Weblog management and operation:

```
blogger.newPost()

blogger.editPost()

blogger.deletePost()

blogger.getRecentPosts()

blogger.getUsersBlogs()

blogger.getTemplate()

blogger.setTemplate()

blogger.getUserInfo()
```

Note:
First name is the Movable Type "username" up to the first space character, and last name is the "username" after the first space character.

14.7.6. MetaWeblog API

```
metaWeblog.newPost()

metaWeblog.editPost()

metaWeblog.getPost()

metaWeblog.getRecentPosts()
```

14.7.7. Movable Type API

```
mt.getRecentPostTitles()

mt.getCategoryList()

mt.setPostCategories()

mt.getPostCategories()

mt.getTrackbackPings()

mt.publishPost()
```

```
mt.supportedMethods()
```

Note:
the value of "appkey" is ignored by Movable Type in all of the Blogger XML-RPC methods.

14.7.8. Atom API

The Atom API is a protocol for publishing and editing a blog entries using the common HTTP verbs:

GET - used to retrieve a blog post or perform query

PUT - used to update an existing blog post

POST - used to create a new post or perform an update action

DELETE - used to remove a post

Authentication. The Atom API implementation accepts both HTTP basic and digest authentication. All requests for post content modification require an authorization. Furthermore, the account used for authentication is checked to be the blog owner or have granted privileges on that particular blog. The retrieval operations; which no post modification is possible are not required to ask for authentication.

Introspection. When editing the content of a blog, the first thing is to find out the servers capabilities. So the 'introspection' file lists all the functions that a given site supports.

Example 14.54. Intropsection

Request:

```
GET /Atom/Http/intro?b=128 HTTP/1.1
Host: example.com
```

Response:

```
HTTP/1.1 200 OK
Server: Virtuoso
Connection: Keep-Alive
Date: Mon, 10 Nov 2003 10:21:55 GMT
Content-Type: text/xml; charset="ISO-8859-1"
Content-Length: 417

<?xml version="1.0" encoding="ISO-8859-1"?>
<introspection xmlns="http://example.com/newformat#" >
  <create-entry>http://example.com/Atom/Http/entry?b=128</create-entry>
  <user-prefs>http://example.com/Atom/Http/prefs?b=128</user-prefs>
  <search-entries>http://example.com/Atom/Http/search?b=128</search-entries>
  <categories>http://example.com/Atom/Http/categories?b=128</categories>
</introspection>
```

Posting a new entry. To post a new entry, the HTTP POST must be performed with MIME type '`application/x.atom+xml` ' for the request content. If server accepts the request a `Location:` HTTP header will be returned to the client containing the URL to the newly created post.

Example 14.55. Posting an Entry

```
POST /Atom/Http/entry?b=128 HTTP/1.1
Content-Type: application/x.atom+xml
Content-Length: nnn
Authorization: ...

<?xml version="1.0" encoding="iso-8859-1"?>
<entry xmlns="http://example.com/newformat#">
  <title>My Entry</title>
  <author>
    <name>Blog Author</name>
  </author>
  <issued>2003-11-04T17:29:29</issued>
```

```
  <content type="application/xhtml+xml" xml:lang="en-us">
    <p xmlns="">Hello world!</p>
  </content>
</entry>
```

The response from server would be:

```
HTTP/1.1 201 Created
Location: http://host:port/Atom/Http/entry?b=128&id=nn
```

Editing an Existing Entry. An entry can be edited via the HTTP PUT method. The URL used for PUT must be one returned by the `Location:` header of the POST response or those returned from entry-search. The content of PUT request is same as for posting a new entry.

Example 14.56. Editing a weblog entry

```
POST /Atom/Http/entry?b=128&id=nn HTTP/1.1
Content-Type: application/x.atom+xml
Content-Length: nnn
Authorization: ...

<?xml version="1.0" encoding="iso-8859-1"?>
<entry xmlns="http://example.com/newformat#">
  <title>My Entry</title>
  <author>
    <name>Blog Author</name>
  </author>
  <issued>2003-11-04T17:29:29</issued>
  <content type="application/xhtml+xml" xml:lang="en-us">
    <p xmlns="">Hello world! (edit test)</p>
  </content>
</entry>
```

The server response is:

```
HTTP/1.1 205 Reset Content
```

Retrieving an Entry. Retrieval of an existing entry is the simple, usual HTTP GET request with URL to the entry.

Example 14.57. Retrieving an Entry

```
GET /Atom/Http/entry?b=128&id=nn HTTP/1.1
Accept: application/x.atom+xml
```

Server will respond with

```
HTTP/1.1 200 OK
Content-Type: application/x.atom+xml
Content-Length: nnn

<?xml version="1.0" encoding="iso-8859-1"?>
<entry xmlns="http://example.com/newformat#">
  <title>My Entry</title>
  <author>
    <name>Blog Author</name>
  </author>
  <issued>2003-11-04T17:29:29</issued>
  <content type="application/xhtml+xml" xml:lang="en-us">
    <p xmlns="">Hello world! (edit test)</p>
  </content>
</entry>
```

Deleting an Entry. To remove permanently an existing entry an HTTP DELETE method is used with URL to the entry.

Example 14.58. Deleting an Entry

```
DELETE /Atom/Http/entry?b=128&id=nn HTTP/1.1
```

Response:

```
HTTP/1.1 200 OK
```

Searching Entries. To retrieve a subset of messages based some criteria a search should be performed. The current implementation supports two variants: range and last_N.

Example 14.59. Searching

```
GET /Atom/Http/search?b=128?last=7 HTTP/1.1
Accept: application/x.atom+xml
Host: example.com
Authorization: ...
```

or

```
GET /Atom/Http/search?b=128&start-range=2&end-range=27 HTTP/1.1
Accept: application/x.atom+xml
Host: example.com
Authorization: ...
```

Response from server will look like:

```
<search-results xmlns="http://example.com/newformat#">
<match title="Classic ASP Framework. Make your Classic...">http://example.com/Atom/Http?b=128&amp;id=6</m
<match title="DB Navigator - an open source .NET control">http://example.com/Atom/Http?b=128&amp;id=4</ma
<match title="Sort an Array with Non-Comparable Items">http://example.com/Atom/Http?b=128&amp;id=5</match
<match title="SignedXML Licensing Sample">http://example.com/Atom/Http?b=128&amp;id=7</match>
<match title="TicTacToe">http://example.com/Atom/Http?b=128&amp;id=1</match>
<match title="Check your eMails in Hotmail using HTTPMail">http://example.com/Atom/Http?b=128&amp;id=2</m
<match title="Slashdot.org RSS Feed Reader">http://example.com/Atom/Http?b=128&amp;id=3</match>
</search-results>
```

Each sub element of the search result contains the title of the post and its URL. These URLs can be used retrieved using the GET method, or modified via PUT/DELETE methods.

Atom Client API

The Atom Client API is a mirror of the blogger API functionality, but uses the Atom protocol instead of XML-RPC. Before the Atom API can be put to use, the introspection file must be retrieved in order to know the URLs for the requests.

- `atom.new_Post (in uri varchar, in req "blogRequest", )`

  This is to post a new entry to the blog identified by 'uri'. The 'req' must be initialized with authentication and entry data. This function returns the URL to the new entry. This could be used with sequential GET/PUT or DELETE requests for it.
- `atom.edit_Post (in uri varchar, in req "blogRequest", )`

  This is to modify an existing entry identified by 'uri'. The 'req' must be initialized with authentication and entry data. The function returns true on success or will signal an error.
- `atom.delete_Post (in uri varchar, in req "blogRequest", )`

  This is to delete an existing entry identified by 'uri'. The 'req' must be initialized with authentication data. The function returns true on success or will signal an error.
- `atom.get_Post (in uri varchar, in req "blogRequest", )`

This is to retrieve an existing post entry identified by 'uri'. The 'req' must be initialized with authentication data. This function will return on success an MTWeblogPost UDT, filled with post entry data.

- `atom.get_RecentPosts (in uri varchar, in req "blogRequest", in num int, )`

  This is to retrieve last-N post entries identified by blog search URL - 'uri'. The 'req' must be initialized with authentication data. 'num' is number of entries to return.

  This function returns an array of arrays containing the title and URL of the matching blog posts.
- `atom.get_Intro (in uri varchar, )`

  This is used to return Introspection information for a blog identified by introspection file - 'uri'.

Example 14.60. Using the Atom Client API

Getting the introspection info about a blog

```
declare x any;
x := atom.get_Intro ('http://example.com/Atom/Http/intro?b=128');
-- x will contain
-- (("create-entry" "http://example.com/Atom/Http/entry?b=128" )
--  ("user-prefs"
-- "http://example.com/Atom/Http/prefs?b=128" ) ("search-entries"
-- "http://example.com/Atom/Http/search?b=128" ) ("categories"
-- "http://example.com/Atom/Http/categories?b=128" ) )
```

make a new entry

```
declare resp any;
declare req "blogRequest";
declare stru "MTWeblogPost";

req := new "blogRequest" ('', '', '', 'dav', 'dav');
stru := new "MTWeblogPost" ();
stru.title := 'My title'
stru.description := '<p>hello</p>';
req.struct := stru;
resp := atom.new_Post ('http://example.com/Atom/Http/entry?b=128', req);
```

The response, resp, would contain: `http://example.com/Atom/Http/entry?b=128&id=1`

edit an entry:

```
declare resp any;
declare req "blogRequest";
declare stru "MTWeblogPost";

req := new "blogRequest" ('', '', '', 'dav', 'dav');
stru := new "MTWeblogPost" ();
stru.title := 'test'
stru.description := '<p>hello from me</p>';
req.struct := stru;
atom.edit_Post ('http://example.com/Atom/Http/entry?b=128&id=1', req);
```

delete it:

```
atom.delete_Post ('http://example.com/Atom/Http/entry?b=128&id=1', req);
```

14.7.9. XML-RPC Endpoint Configuration

The Virtuoso blog server can be contacted directly by SOAP XML-RPC. A virtual directory can be created with blogger APIs (Blogger, MetaWeblog, MoveableType, Atom) ability, which requires a mapping to the SOAP endpoint and grants to use the blogger API. This can be done in two ways:

1. **Using the graphical Server Administration Interface.** You can use your web browser to configure a virtual directory based on the "XML-RPC link" template and with bloggerAPI enabled:

    a. Open a web browser on the Administration User Interface and navigate to: Internet Domains; HTTP Virtual Directories; Edit URL mappings.
    b. Create a new virtual directory.
    c. Select the template for "XML-RPC link".
    d. Check the option 'bloggerAPI' is enabled, this will expose all available blogger APIs to the endpoint (Blogger, MetaWeblog, MoveableType, Atom).
    e. Configure the logical path.
    f. Click Add to save the definition.

    See Also:

    Virtual Directory Administration UI

    vhost_define()

    vhost_remove()

    The new logical path now will support XML-RPC and will support blogger API requests.
2. **Programmatical: Script & ISQL.** This method gives you full control, you must perform all steps to allow full support for the blogger API on a virtual directory. Below is a template list of commands that could be in a script.

    Using a script, `blogserver.sql` , with following contents:

```
vhost_define (
  lpath=>'/RPC2',
  ppath=>'/SOAP/',
  soap_user=>'$U{usr}',
  soap_opts=>vector ('XML-RPC', 'yes')
  );

grant execute on "blogger.newPost" to $U{usr};
grant execute on "blogger.editPost" to $U{usr};
grant execute on "blogger.deletePost" to $U{usr};
grant execute on "blogger.getPost" to $U{usr};
grant execute on "blogger.getRecentPosts" to $U{usr};
grant execute on "blogger.getUsersBlogs" to $U{usr};
grant execute on "blogger.getTemplate" to $U{usr};
grant execute on "blogger.setTemplate" to $U{usr};
grant execute on "blogger.getUserInfo" to $U{usr};
grant execute on "metaWeblog.newPost" to $U{usr};
grant execute on "metaWeblog.editPost" to $U{usr};
grant execute on "metaWeblog.getPost" to $U{usr};
grant execute on "metaWeblog.getRecentPosts" to $U{usr};
grant execute on "mt.getRecentPostTitles" to $U{usr};
grant execute on "mt.getCategoryList" to $U{usr};
grant execute on "mt.setPostCategories" to $U{usr};
grant execute on "mt.getPostCategories" to $U{usr};
grant execute on "mt.getTrackbackPings" to $U{usr};
grant execute on "mt.publishPost" to $U{usr};
grant execute on "mt.supportedMethods" to $U{usr};
```

    One can start ISQL using the following parameters:

```
$ isql 1111 dba dba -u usr="<SQL user for execution>" blog_server.sql
```

    Where "<SQL user for execution>" is an existing SQL user account other than dba.

Note:

Note:

If you specify the "dba" as user for SOAP execution in a virtual directory, the grant statements will not be needed and this will open a security hole. So this approach is not recommended. It is always better to have a separate user for SOAP execution with limited rights.

14.7.10. Blog Hooks - Customizing the Blog Server

Virtuoso provides the default system for blogging using one of the supported . Virtuoso provides several PL hooks to customize the blog server. The following hooks are available for definition:

authenticate_<appkey> (in req blogRequest)

newPost_<appkey> (in req blogRequest)

editPost_<appkey> (in req blogRequest)

deletePost_<appkey> (in req blogRequest)

getPost_<appkey> (in req blogRequest)

getRecentPosts_<appkey> (in req blogRequest, in numberOfPosts int)

See Also:

XML-RPC section

blogRequest is a UDT defined as follows:

```
create type "blogPost" as (
                          "content" varchar,            -- message
                          "dateCreated" datetime,       -- timestamp
                          "postid" varchar,             -- message ID
                          "userid" int                  -- creator
                        ) temporary self as ref
;

create type "blogRequest" under "blogPost"
                        as
                        (
                          user_name varchar,            -- user name
                          passwd varchar,               -- credentials
                          appkey varchar,               -- application key
                          blogid varchar,               -- web log ID
                          postId varchar,               -- message ID
                          auth_userid integer,          -- user ID
                          publish smallint,             -- not used, but still in API
                          struct DB.DBA.MWeblogPost     -- used in WebMetaLog
                        ) temporary self as ref

constructor method blogRequest (
                          appkey varchar,
                          blogid varchar,
                          postId varchar,
                          user_name varchar,
                          passwd varchar
                          )
;
```

Example 14.61. Customizing the BLOG Server

```
-- SIMPLE BLOG APPLICATION
-- application key: 0123456789
--
-- the following UDTs are used in API calls
--
-- single message
-- create type "blogPost" as (
--                         "content" varchar,
--                         "dateCreated" datetime,
--                         "postid" varchar,
--                         "userid" int
--                       ) temporary self as ref
--
```

```
--
-- a blog request
-- create type "blogRequest" under "blogPost"
--                       as
--                       (
--                         user_name varchar,
--                         passwd varchar,
--                         appkey varchar,
--                         blogid varchar,
--                         postId varchar,
--                         auth_userid integer,
--                         publish smallint
--                       ) temporary self as ref
--
-- as metaWeblog API not not have appkey, we are assuming 'META_WEBLOG' for it.

drop table BLOG;

create table BLOG (
                        B_APPKEY varchar,
                        BLOG_ID varchar,
                        B_CONTENT long varchar,
                        B_POST_ID varchar,
                        B_TS timestamp,
                        B_USER_ID integer,
                        primary key (B_APPKEY, BLOG_ID, B_POST_ID)
);

-- APPLICATION LEVEL HOOKS
create procedure authenticate_app (inout req blogRequest)

     post."userid" := B_USER_ID;
     ret := vector_concat (ret, vector (post));
     numberOfPosts := numberOfPosts - 1;
     if (numberOfPosts <= 0)
       goto endg;
   }
endg:
  return ret;
}
;
```

14.7.11. Blogger Client API

`varchar` **`blogger.new_Post`** (in *uri* varchar, in *req* "blogRequest", in *content* varchar) ;

`boolean` **`blogger.delete_Post`** ((in *uri* varchar, in *req* "blogRequest")) ;

`boolean` **`blogger.edit_Post`** ((in *uri* varchar, in *req* "blogRequest", in *content* varchar)) ;

`blogPost` **`blogger.get_Post`** ((in *uri* varchar, in *req* "blogRequest")) ;

vector **blogger.get_Recent_Posts** ((in *uri* varchar, in *req* "blogRequest", in *lim* int)) ;

Example 14.62. The Blogging Client

Create a new message.

```
SQL> select blogger.new_Post ('http://example.com/RPC2',
    blogRequest ('0123456789', 'home', '', 'dav', 'dav'),'test');
callret
VARCHAR
_______________________________________________________________________________

6

1 Rows. -- 267 msec.
```

Edit a message created with previous step:

```
SQL> select blogger.edit_Post ('http://example.com/RPC2',
    blogRequest ('0123456789', 'home', '6', 'dav', 'dav'), 'test edited');
callret
VARCHAR
_______________________________________________________________________________

1

1 Rows. -- 194 msec.
```

Get the message, result will be in a blogPost UDT:

```
SQL>  dbg_obj_print (blogger.get_Post ('http://example.com/RPC2',
      blogRequest ('0123456789', 'home', '6', 'dav', 'dav')));

Done. -- 120 msec.

---- server console ----
{
        REF:[ref:0xa0deb00 obj:0xa1ed168 DB.DBA.blogPost]
        content=N"test edited"
        dateCreated={ts 2003-04-08 15:34:13.000000}
        postid=N"6"
        userid=2
}
------------------------
```

get list of messages, in our case the result will be a vector with one element of blogPost UDT.

```
SQL> dbg_obj_print (blogger.get_Recent_Posts ('http://example.com/RPC2', blogRequest ('0123456789', 'home

Done. -- 124 msec.

---- server console ----
({
        REF:[ref:0xa2426a8 obj:0xa20af40 DB.DBA.blogPost]
        content=N"test edited"
        dateCreated={ts 2003-04-08 15:34:13.000000}
        postid=N"6"
        userid=2
}
 )
------------------------

<programlisting><![CDATA[
SQL> select blogger.delete_Post ('http://example.com/RPC2',
    blogRequest ('0123456789', 'home', '6', 'dav', 'dav'));
callret
VARCHAR
_______________________________________________________________________________
```

```
1

1 Rows. -- 337 msec.
```

There are more examples on using the API in the tutorials.

14.7.12. xmlStorageSystem API

xmlStorageSystem is an Web storage system for documents that are programmable over XML-RPC and SOAP 1.1. Uploaded files are accessible via HTTP. xmlStorageSystem has methods that allow users to register with the service; upload a set of files; query the server to find out its capabilities; and to register a notification request.

See Also:
XML-RPC section

The API methods are:

```
xmlStorageSystem.registerUser()
xmlStorageSystem.mailPasswordToUser()
xmlStorageSystem.getServerCapabilities()
xmlStorageSystem.deleteMultipleFiles()
xmlStorageSystem.saveMultipleFiles()
xmlStorageSystem.requestNotification()
```

Relation to the WebDAV Repository

The xmlStorageSystem stores uploaded files in the WebDAV repository. Upon user registration a "blog" sub-folder will be created in the user-account home directory, into which these files will be uploaded and stored using the xmlStorageSystem API.

Authentication. The XML Storage System uses WebDAV enabled accounts to authenticate. The passwords sent via the xmlStorageSystem API (except registerUser, see below) must be an MD5 hash of the real user password. In this way clear text password cannot be captured from network sniffers.

Cloud notification services. The aggregators scan for changes in an interval, but in some situations we want to know when a channel has changed immediately. Notification makes it possible to always be in sync with bandwidth conservation and unneeded loops. This is possible to register an aggregator using a xmlStorageSystem.requestNotification function, also to make aggregator to know about such service it's parameters are exposed in <cloud> sub-element of <channel> of the RSS files. The notification works as follows: aggregator gets registered via xmlStorageSystem.requestNotification; Then if a registered link changes, the aggregator will be notified via specified protocol and method. The aggregator needs to register itself every 24 hour, otherwise the registration will expire. For full explanation of the cloud element of RSS file see reference at "http://backend.userland.com/rss#ltcloudgtSubelementOfLtchannelgt".

Enabling XML Storage System in a Virtual Directory

The XML Storage System can be enabled by creating a virtual directory as a SOAP enabled directory, where the SOAP users is set to DBA or any other user granted execute permissions to the xmlStorageSystem methods.

Example 14.63. Enabling an xmlStorageSystem Virtual Directory

via ISQL tool:

```
SQL> vhost_define (lpath=>'/xmlStorageSystem', ppath=>'/SOAP/',
    soap_user=>'dba');
```

The xmlStorageSystem takes into account the following user options:

maxFileSize, integer - maximum file length allowed for upload

maxBytesPerUser, integer - maximum total bytes

These are set upon initial registration to 1Mb/40Mb respectively and can be changed via the Visual Server Administration Interface -> WebDAV -> WebDAV users -> Options link.

14.7.13. User's Blog quota

In reality blog users are going to consume data space via weblog posts. For maximum flexibility to blog host administrators the following quotas are available:

"Post Quotas": A maximum number of posts "Cumulative Post Size": A threshold that is based on a cumulative size of posts. These are settable to a user which may do a blog posts via WebDAV - User accounts UI.

14.7.14. Posting a message in to the Blog

To post a message to the blog usually is used various tools implementing a blogger APIs as clients. These are standalone tools running on a PC or other platform, but not in all cases one have these tolls on hand. Therefore a web interface is needed. The default home page (index.vspx) implements authentication schema and allows blog owners to post to their blogs. To login to that page blogger should go to the site home page and when supply valid credentials will be authenticated and thus possible to make posts/edit existing etc. For authenticated user in that case is also possible to change details, settings channel subscriptions.

14.7.15. Multi-author blogging

In many cases many people needs authoring in common blog. For that case web admin have to create a blog which is owned by "group" (not by web user) and then granting this role to users which are authors will give them access to post on that blog. As group cannot be authenticated, thus it's not possible to login as group and post on behalf of it; the post's author have to be a valid web user account. This feature does not contradict with possibility authors to have their own blogs, they can have own and post to many "group" blogs. Granting access to a "group" blog can be done via WebDAV users UI, or with GRANT statement via ISQL tool.

14.7.16. Posting a comments

The blog is a something that one person or group of persons (authors) exposing to the public. So in some cases this material may need commentary from other people than authors. This is a option to the blog settings, when it's enabled (default) the home page of the blog (via permaLink) will offer a post form to make a comment. When making a comment the author's details can be recorded and re-used based on cookie; comment poster may control that option. Once comment is posted it can be read in same place (permaLink) as in discussion group.

14.7.17. Blog Post Upstreaming (bridging)

The blog upstreaming allows bloggers to keep in sync their blogs on different servers. It is possible for blogger to define a routing target, where his/her posts will be sent after local post is made, updated or deleted. This feature using blogger APIs (Blogger, MetaWeblog, MovableType) to pass messages to the remote. Therefore the target server must support one of these APIs.

The upstreaming works in following manner:

The blogger defines a routing job, which is of type "Upstream". To do this can be used Weblog Bridge UI following the steps: enter the XML-RPC endpoint, username and password valid there; hit "Fetch" to retrieve blogs on that host where the account can post; select desired account ; specify a time interval for update and which categories of posts to exclude; press "add" button.

This is is a equivalent of executing a simple insert statement :

```
SQL> INSERT INTO DB.DBA.SYS_ROUTING
        (
        R_JOB_ID,
        R_TYPE_ID,
        R_PROTOCOL_ID,
        R_DESTINATION,
        R_DESTINATION_ID,
        R_AUTH_USER,
        R_AUTH_PWD,
        R_ITEM_ID,
        R_FREQUENCY,
```

```
        R_EXCEPTION_ID)
        VALUES
        (
        1,      -- unique for job
        1,      -- Upstreaming job
        1,      -- Blogger API (2 for metaWeblog, 3 from mt)
        'http://example.com/RPC2', -- target endpoint
        'home', -- target BlogID
        'visitor', -- user
        'secret',  -- secret
        '128',     -- local Blog ID (which to replicate)
        60,        -- hourly update
        '0;1;'     -- exclude posts within categories with ID 0 and 1
        );
```

This will make so when post is added/edited/deleted to make entry(es) in SYS_BLOGS_ROUTING_LOG table. Then on specified R_FREQUENCY a scheduled job will make blogger XML-RPC requests to the target server using API as specified in R_PROTOCOL_ID field. If target server is down the entries will be kept for next job round.

The upstreaming feature can be extended easily to make another form of routing. The e-mail notification services in blogging is just one of them.

The following shows how this feature can be triggered with simple insert command:

```
INSERT INTO DB.DBA.SYS_ROUTING
        (R_JOB_ID,R_TYPE_ID,R_PROTOCOL_ID,R_DESTINATION,R_ITEM_ID,R_FREQUENCY,R_EXCEPTION_ID)
        VALUES(
        2,  -- unique for job
        2,  -- Email notification
        4,  -- STMP protocol
        'mail.domain.com:25', -- mail server
        '128', -- local Blog ID
        10,     -- scan every 10 minutes
        '0;1;'  -- exclude posts within categories with ID 0 and 1
        );
```

The same can be done via Weblog UI - Notification setup

14.7.18. Weblogs API

This API consists of "weblogUpdates.ping" XML-RPC call and server-side implementation.

The blog owner may enable weblogs pings as option in the blog settings. Then when it's blog gets updated a ping request will be sent on periodic basis to the "http://rpc.weblogs.com/weblogUpdates" server.

The server also implements weblogUpdates.ping method. If this method is exposed on a XML-RPC enabled endpoint, other parties may use it for notification.

The server implementation consist of : weblogUpdates.ping (in weblogname varchar, in weblogurl varchar, out Result struct). The party sends a ping with blog name and url and receive a common for blogger API response as struct (flError boolean, message varchar). Also a public accessible http://host:port/blog/weblogs.xml file is available for aggregators to track the latest additions made via Weblogs ping call. Please note that this file generates during on weblog site setup. hence we will have this file only if community blog pages are generated.

The weblogs.xml file follows the XMLSchema below:

```
<?xml version="1.0" encoding="UTF-8"?>
<xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema" elementFormDefault="qualified">
  <xs:element name="weblog">
    <xs:complexType>
      <xs:attribute name="name" type="xs:string" use="required"/>
      <xs:attribute name="url" type="xs:string" use="required"/>
      <xs:attribute name="when" type="xs:int" use="required"/>
    </xs:complexType>
  </xs:element>
  <xs:element name="weblogUpdates">
    <xs:complexType>
```

```
      <xs:sequence>
        <xs:element ref="weblog" maxOccurs="unbounded"/>
      </xs:sequence>
      <xs:attribute name="version" type="xs:string" use="required" fixed="1"/>
      <xs:attribute name="updated" type="xs:string" use="required"/>
      <xs:attribute name="count" type="xs:int" use="required"/>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

14.7.19. Subscriptions

Every blogger read and link to it's blog a many other sources, which are usually RSS feeds or other Web content. As RSS feeds (doesn't matter in which format RSS/RDF) are common practice to offer XML data from blogs, this is preferable source for most of the bloggers. The utilities for collecting such data are known as aggregators.

The blogging support implements a own channel/blog aggregator, so bloggers may import RSS as specifying a URL to it, or using a directory formats as OCS and OPML. Secondly the channel feeds requested by blogger will be refreshed on a periodic basis (depending of channel parameters) and will feed the data locally. Once the channel is refreshed a blogger may do "BlogThis!" when browsing the local copy of the channel. This function is available via Admin UI - Weblog UI, or via "Channels" on blog home page when owner is authenticated.

14.7.20. Trackback API

The TrackBack provides a method of notification between websites: it is a method of person A saying to person B, "This is something you may be interested in." To do that, person A sends a TrackBack ping to person B. TrackBack ping call: this is a small message sent from one webserver to another via HTTP POST or GET. There are few situations where track back is useful: *As a form of remote comments rather than posting the comment directly on person B's weblog, person A posts it on his own weblog, then sends a TrackBack ping to notify person B. *Person A has written a post that group of people are interested in; then it sends a trackback to a community server and there visitors can show it.

The implementation consist of : * the "trackback" method which can be invoked via REST(HTTP POST) * auto-discovery of the trackback URL in default blog home page

trackback (varchar id, varchar url, varchar title, varchar excerpt, varchar blog_name, varchar __mode) the method can be invoked via REST and returns a XML response.

A typical trackback post request look-like as :

```
POST /mt-tb/Http/trackback?id=1
Content-Type: application/x-www-form-urlencoded
title=Some+Title&url=http://www.some.domain/&excerpt=An+excerpt&blog_name=foo
```

A successful trackback response :

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<response>
  <error>0</error>
</response>
```

When "__mode" parameter is specified via GET request, then trackback method returns a RSS v0.91 XML data for given post enclosed in response element.

A sample request and response follows:

```
http://host:port/mt-tb/Http/trackback?id=3&__mode=rss

<response>
<error>0</error>
<rss version="0.91">
<channel>
  <title/>
  <link> http://....  </link>
  <description> Description text ....  </description>
</channel>
```

```
</rss>
</response>
```

14.7.21. Pingback API

The Pingback is another form of trackback, just protocol and parameters are different. In Pingback is used XML-RPC instead of REST model. Also the requester sends his own and target url as part of request.

The implementation consists of "pingback.ping" XML-RPC method and auto-discovery in blog home page.

"pingback.ping" (in sourceURI varchar, in targetURI varchar) return varchar

The sourceURI is URL for page of requester; targetURI is page on the target server. The pingback.ping method will retrieve sourceURI and will record the data as trackback it targetURI exists on same server and it's valid permaLink. On success it returns a string 'Success' otherwise XML-RPC error code.

Pingback 1.0

14.7.22. E-mail Notifications

The blog implementation offers a two kind of notifications: notify via e-mail a blog owner when a comment is posted; or one could subscribe to receive blog posts via e-mail. Both notifications are disabled by default and can be turned on using Weblog UI. When this flag is on a scheduled job will send e-mail to the blogger for every new comment posted to the given blog.

The blog owner notification can be turned on as setting BI_COMMENTS_NOTIFY to 1 in table SYS_BLOG_INFO for corresponding blog entry. Other way is to use Weblog settings UI.

If blog owner decide, can define a notification route. To do that he can add a routing job of type SMTP to the routing table. See "Blog Upstreaming" discussed earlier in this chapter how to do that. Also it's possible via Weblog settings UI to add such route via "Notification" link. Note that when define such route , better practice is to designate a category which to be considered as for subscription.

Once such routing job is defined for given blog, users can subscribe and therefore receive e-mails for posts which blogger assign to a category for notification.

14.7.23. Comments tracking options

When a blogger enable E-mail Notification for comments on his/her blog, the following options are available:

HTML - the notification will be sent in HTML format, the message will contain URLs to the post and comment API. Reply to this mail will add new comment, if mail-gateway is enabled by Web administrator.

HTML Form - this option will send an email containing comment and form, which could be used to invoke directly comment API from mail agent (if it supports posting a form)

Text - this option is same as first, but uses plain text instead of HTML encoding.

combined : combines all of the above as attachments.

14.7.24. Subscription Harmonizer API

Considering situation where blogger have many subscribed channels and wish these to be in sync on different places it usually subscribe/unsubscribe in home, work public blog. To be easiest for one to keep all mirrored blog instances (see Upstreaming discussed above) to have same channel subscription can be used Subscription Harmonizer API. This API consist of four methods available via XML-RPC , so developers can use them to put in sync blogger channel subscriptions.

"subsHarmonizer.setup" (in username varchar, in "password" varchar, in array any) This is used to setup on server channels which are subscribed locally. The user authenticates using name and password and sends to server list of RSS URLs in "array" parameter. This action is usually performed once , on initial subscription.

"subsHarmonizer.subscribe" (in username varchar, in "password" varchar, in array any) This is used when in local blog instance blogger makes new subscription(s), the "array" will contains only entries have been added since last call to that or subsHarmonizer.setup call. The target server will resolve URL list and will make records in SYS_BLOG_CHANNEL and SYS_BLOG_CHANNEL_INFO tables.

"subsHarmonizer.unsubscribe" (in username varchar, in "password" varchar, in array any) This function is opposite of subsHarmonizer.setup , it is used when blogger unsubscribe from some channels. The server action is to remove channel subscriptions from blog instance. Note that in this case server keeps channel definition , so it can be re-used when another user get subscribed to it, this is to minimize bandwidth consumption for channel characteristics retrieval.

All of the above returns boolean.

"subsHarmonizer.startup" (in username varchar, in "password" varchar) This function is used from blog application to get from server list of subscriptions which are currently registered. In that case blog application uses the array of URLs returned to set it's local list of channels.

14.7.25. Mobile Blogging (Moblog)

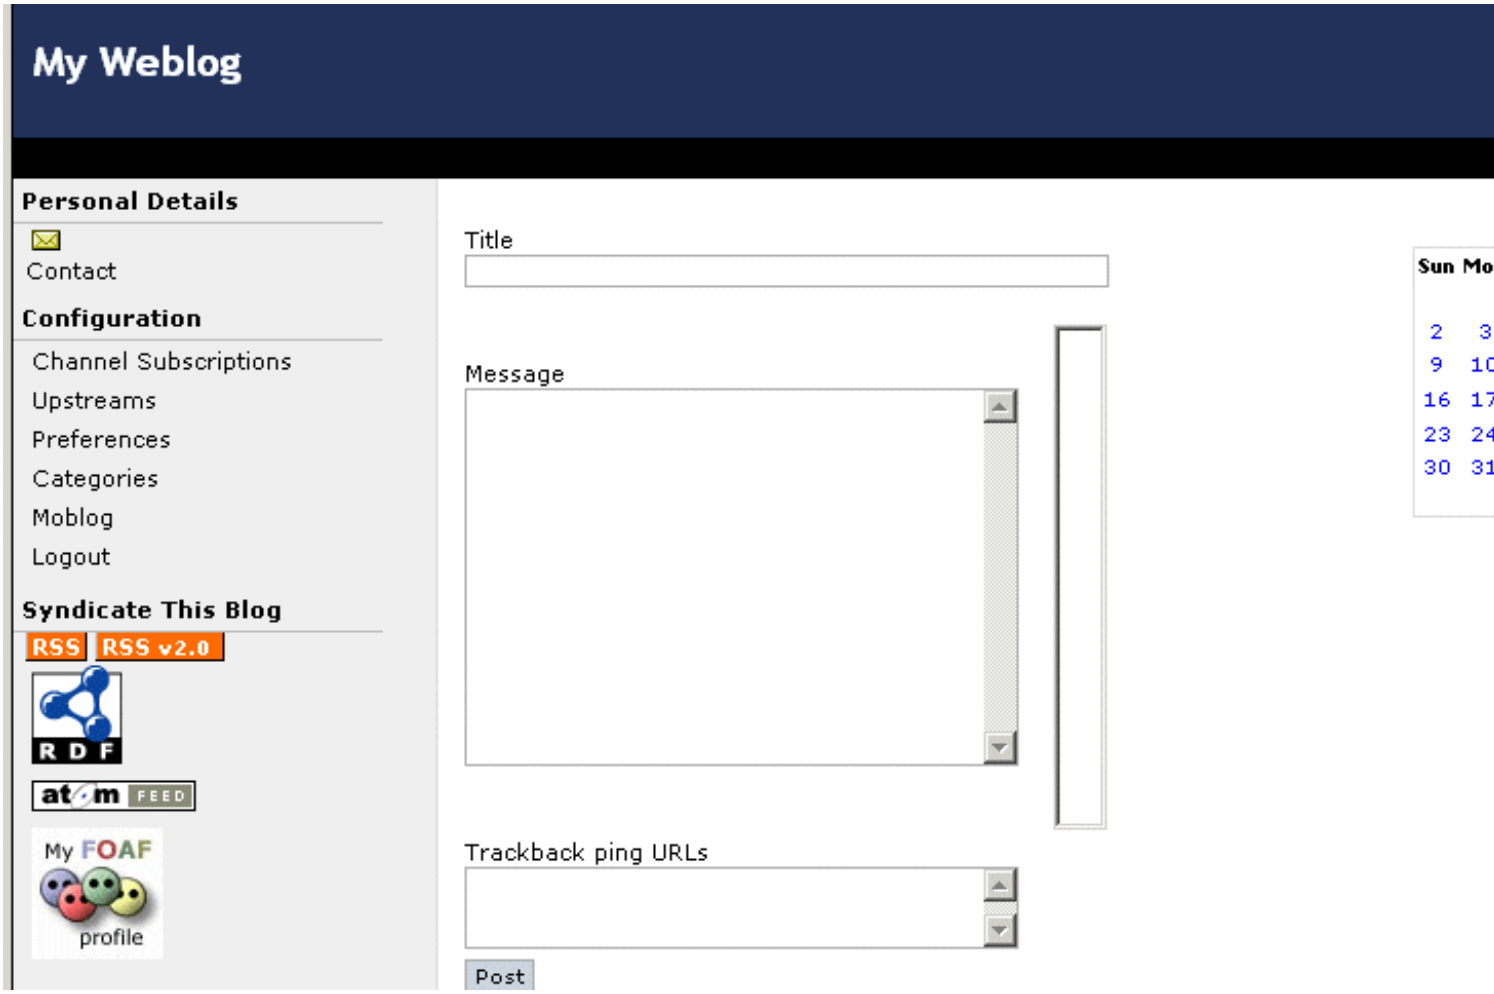
The Mobile blogging (moblog) is synonym of messages containing images made via mobile devices (such as mobile telephones etc.) with ability to record a image and send them via SMTP.

Moblog"ing has become popular as means for users to easily, automatically and immediately post text and images back to their blog site what ever their location.

The Virtuoso server can act as mail server (see Storing Email in Virtuoso chapter, and howto configure mail servers in same chapter). Thus it"s possible to capture mails sent via mobile devices and expose in a Blog. But main problem remains: SMTP have no authentication. So this functionality is achieved via UI which shows all existing mail messages sent via mobile devices and containing a images, allowing to the blog owner to decide which image to go to his/her blog. As an alternative post can be automatic if blogger check this option.

Mobile blogging (Moblog) can be configured via the Virtuoso blog UI by selecting the Moblog link under the Configuration section as indicated in the diagram below:

Figure 14.51. Blog page



The Moblog configuration page enables the details of the POP3 server from which messages are to be retrieved from is located as indicated in the diagram below:

Figure 14.52. Blog page

- *Server Address and Port*

- Hostname and port number of the POP3 Mail Server.

- *Account Username*

  - username of POP3 Mail server account.

- *Account Password*

  - username of POP3 Mail server account.

- *Enable Automatic Moblogging*

  - enabled automatic posting of messages to Blog site.

- *Allowed MIME types*

  - mime type of messages to be retrieved form POP3 server, which can be of type image, vidoe or audio.

- *Set*

  - this button sets the POP3 mail server setting entered above.

- *Fetch*

  - this button retrieves available moblog messages from the POP3 mail server.

Moblog can handle different types of attachments, this depends of list of MIME type patterns (SQL like syntax), which blogger specifies in Moblog UI. Further any new incoming message containing attachment matching any of that list will be exposed in the UI for posting, or it will be posted automatically if "Automatic post" option is checked.

Note: feeding a mail box can also be done via "Mail", "Get Mail with POP3" Admin UI utility. In this case blogger authenticates in this utility, and feeds it"s local mailbox from some POP3 server. The consequential actions to put a message as blog message are same as described above.

As alternative to feeding via own POP3 account, Moblog message can be sent to special mail-gateway account. Such account can be set from Web admin only and can be used from all bloggers to pass Moblog messages to their blogs. Only requirement in that case is blogger to include "@@blogId@@=[blog Id]" string as a single line whenever in the message body. Further mail-gateway processing will detect such rule and will expose the message in the Moblog UI, or automatic post will be performed.

14.7.26. Posting a dynamic content

The Virtuoso blogging system allows to insert into a post a result from SQL, XPATH or XQuery expressions. The way this can be done is to have a SQL access enabled for the Web user making the post, so such blogger can insert into a post body (note that this is not available for title) a XMLTemplate. (see "XML Templates" for reference) Then at the render time the template will be executed on behalf of the blogger who is made the post and result will be shown. There is no limitation how many XML Templates can be included in a single post. Please note that bloggers without SQL access cannot do such posts. Also the SQL granting rules will be applied when XML Template is executed.

The following will render a simple table containing list of Demo.demo.Shippers table from Demo database.

```
<table border="1">
    <sql:query xmlns:sql="urn:schemas-openlink-com:xml-sql" >
        select 1 as tag , null as parent, CompanyName as [tr!1!td!element]
        from Demo.demo.Shippers
        for xml explicit
    </sql:query>
</table>
```

The following post will render a table containing a names of people which is organized in simple OPML file (located in the tutorial system) using XQuery.

```
<div>
    <sql:xquery  xmlns:sql="urn:schemas-openlink-com:xml-sql"
        sql:context="http://example.com/tutorial/apps/blog_query/">
        <![CDATA[
        <table border="1">
            { for $o in document ("opml.xml")//outline
               return <tr><td>{ string ($o/@text) }</td></tr>
            }
```

```
            </table>
            ]]>
          </sql:xquery>
        </div>
```

14.7.27. Notification Services

This UI is used to define a mail routing job. So it is used for notification of blog visitors for post updates. If administrator define a mail target and refresh interval; visitors to the given blog can subscribe to the 'mailing list' for blog updates. Once visitor have subscribed, on every new post an email will be sent to he/she. If the mail is deleted, the mailing list for blog update notification will be canceled.

14.7.28. Rendering the RSS feed in WML format

The user's blog RSS file could be rendered in WML format for accessing with mobile devices. To do that built-in PL post-processing hook for blog virtual directory is introduced (DB.DBA.BLOG_RSS2WML_PP). It working together with a XSL-T style-sheet which converts the RSS in WML format.

To enable this functionality the blogger should enter '*wml-default*' as RSSFilter option on settings page. Or if he/she has an own XSL-T filter for WML can enter its URL instead.

The DB.DBA.BLOG_RSS2WML_PP post-processing hook:

```
create procedure DB.DBA.BLOG_RSS2WML_PP ()
  {
    declare accept, upar, pars any;
    declare lines any;
    lines := http_request_header ();
    accept := http_request_header (lines, 'Accept');
    if (not isstring (accept))
      accept := '';
    upar := http_request_get ('QUERY_STRING');
    if (regexp_match ('text/vnd\.wap\.wml', accept))
      {
        if (http_path () like '%/rss.xml')
          {
            declare opts, filt, bid any;
            whenever not found goto exitp;
            select top 1 BI_BLOG_ID into bid from SYS_BLOG_INFO where
            http_path () like BI_HOME || '%' order by length (BI_HOME) desc;
            select deserialize (blob_to_string (BI_OPTIONS)) into opts from SYS_BLOG_INFO where BI_BLOG_I

            if (not isarray(opts))
              opts := vector ();

            filt := get_keyword ('RSSFilter', opts, '');

            if (filt = '*wml-default*')
              filt := 'http://local.virt/rss2wml.xsl';

            if (not isstring (filt) or not xslt_is_sheet (filt))
              goto exitp;

            if (length (upar) = 0)
              {
                http_xslt (filt);
              }
            else
              {
                declare rss, xt, xsl any;
                rss := http_get_string_output ();
                xt := xml_tree_doc (rss);
                http_rewrite ();
                xsl := xslt (filt, xt, vector ('id', upar));
                http_value (xsl, null);
              }
            http_header ('Content-Type: text/vnd.wap.wml\r\n');
            exitp:;
          }
```

```
        }
      return;
    }
;
```

The rss2wml.xsl style sheet:

```
<?xml version='1.0'?>

<xsl:stylesheet

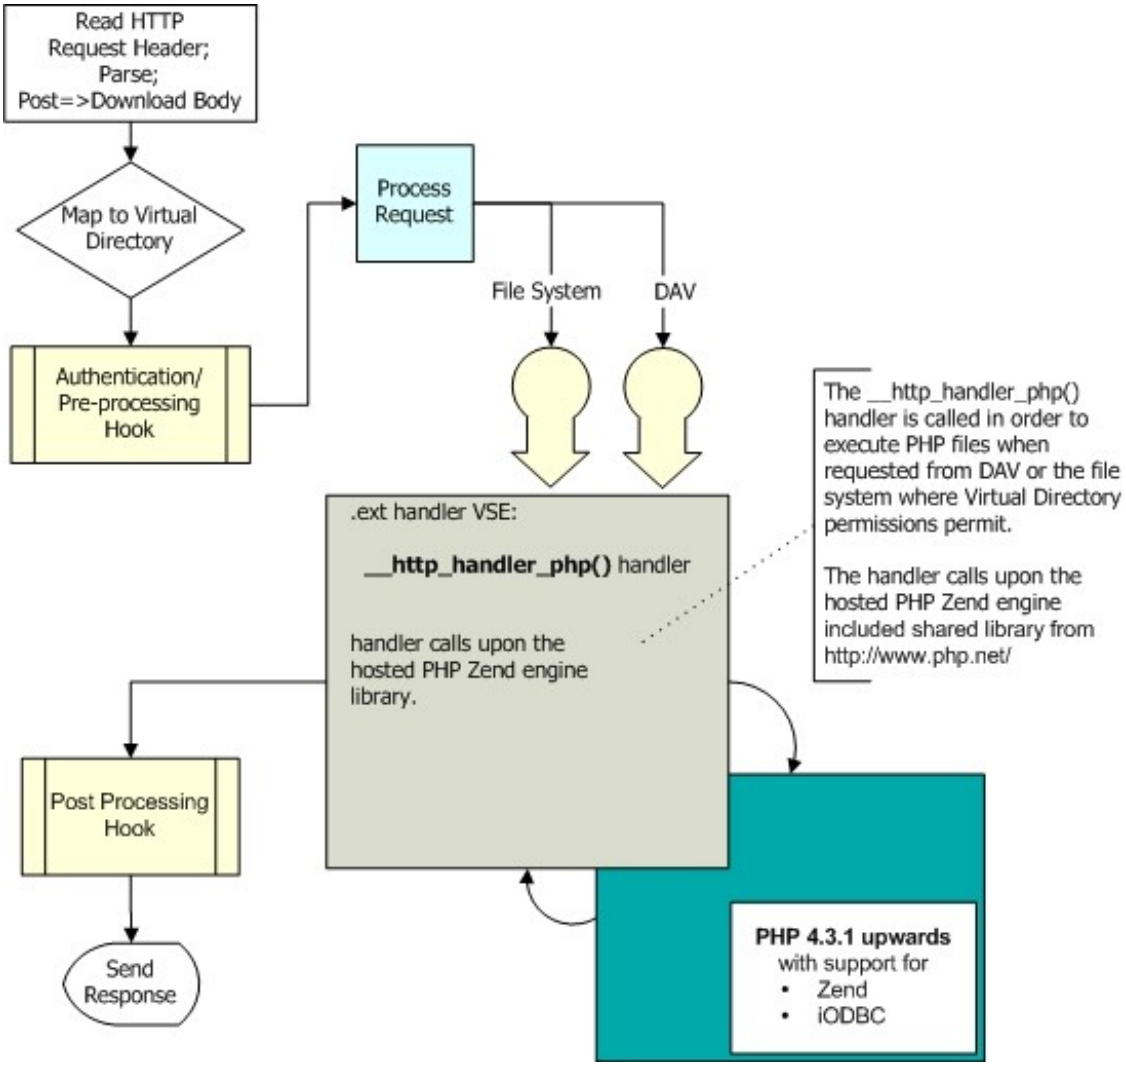
            <xsl:value-of select="title"/>
          </a>
        </p>
      </xsl:otherwise>
    </xsl:choose>
  </xsl:template>

  <xsl:template match="text()"/>
</xsl:stylesheet>
```

14.8. Deploying PHP Applications

The PHP server extension allows Virtuoso to execute PHP (v4) pages stored in the file system or in Virtuoso's WebDAV repository. PHP pages run inside the Virtuoso process.

Figure 14.53. The HTTP PHP handler



The VSE __http_handler_php() has been implemented so that the file extension '.php' is recognized by Virtuoso to switch between 'normal' mode and extension processing for PHP mode in the HTTP/WebDAV services.

PHP (recursive acronym for "PHP: Hypertext Preprocessor") is a widely-used Open Source general-purpose scripting language that is suited for Web-based development. Here is an example of a simple PHP page:

Example 14.64. PHP introductory example

```
<html>
    <head>
        <title>Example</title>
    </head>
    <body>

        <?php
        echo "Hi, I'm a PHP script!";
        ?>

    </body>
</html>
```

Notice how this is similar to VSP script, and different from a script written in other languages like Perl or C -- instead of writing a program with lots of commands to output HTML, you write an HTML script with some embedded code to do something. The PHP code is enclosed in special start and end tags that allow you to jump into and out of "PHP mode".

PHP Online Documentation

In-Process Data Access Client

14.8.1. Building the Virtuoso Server With PHP Extension

1. Firstly you need to have the PHP4 library installed with Zend and ODBC interface enabled. On UNIX-es this can be enabled by doing 'configure --enable-experimental-zts --with-iodbc'. On Windows the library must be downloaded from the php.net site.
2. Make sure that the iODBC library is installed if you are preparing to build on UNIX platform.
3. Make the bif_server_php executable in the bifsdk/examples/ directory. This same directory contains the source file for the bif_server_php executable: bif_server_php.cpp.

The Virtuoso distribution may already contain a binary executable of the PHP extension of the Virtuoso's Web Service. In which case you may skip the build process and start the server with the PHP extensions instead of starting the normal virtuoso server executable.

To start and test the Virtuoso server with the PHP extension do the following:

1. Make a simple file 'info.php' and place it in the HTTP root directory. The content of the info.php file should be the single line:

   ```
   <?phpinfo();?>
   ```

   This function produces an HTML page containing various PHP processor information.
2. Start the server. For Linux platform: bif_server_php -f, for Windows platform: bif_server_php-odbc-t.exe -f
3. Test the installation by entering the http://[host:port]/info.php as the URL of a browser of your choosing.

Note:
Windows users will need to install the php4ts.dll (from the php.net site) before running the PHP enabled Virtuoso server. This DLL must be in the system path when Virtuoso starts and can typically be placed in the %SYSTEMROOT% directory without any path modifications.

Note:
The PHP library used with Virtuoso must be version 4.3.1 or greater. From this version the PHP library includes a serious PHP CGI vulnerability fix, without which the Virtuoso server will fail to start for security reasons.

14.8.2. PHP Extension Functions

The following functions have been added to the Virtuoso server in order to enable PHP processing.

PHP Server Handler.

__http_handler_php (in *file_name* varchar,
in *params* vector (opt1, value [,...]) or string session,
in *lines* vector (opt, value[,...]),
inout *what* any) ;

This function will be detected and called automatically by the Virtuoso HTTP/WebDAV server when a request for a file with extension .php is made.

- The

  file_name

  argument will be the path to the file when the PHP page is stored on the file system or the actual content of the page when a WebDAV resource is processed.
- The content of request entity body will be stored in a string session and passed down to the __http_handler_php as the

  params

argument.

- The HTTP request header will be passed as the

  lines

  argument.
- The

  what

  parameter is used for in two ways: to indicate whether the first argument is a path/file name to a file on the filesystem or the content of the required WebDAV resource. The HTTP/WebDAV server will return an array of two elements to this parameter.

PHP Processor.

__http_php_str (in *string* varchar,
in *params* vector (opt1, val1 [,...]) , varchar) ;

This function takes a string containing PHP code (page), and parameters supplied in the params array and returns the result from the PHP engine as a string. This can be useful for performing PHP transformations in PL or VSP code.

- the

  string

  is the source of the PHP page
- *params*

  is a string or array of strings containing parameter name and parameter value pairs. In the case of a single string it must contain form parameters in the application/x-www-form-urlencoded encoding. In case of an aref of strings it must contain the name and value for parameters. (Like the params argument in the VSPs).

14.8.3. PHP Examples

Example 14.65. Examples of the php_str() usage

Unless the examples are shown as executed in the ISQL tool, this can be made also in the Virtuoso/PL code.

```
SQL> select php_str ('<?php echo "Hello World"?>');
callret
VARCHAR
_______________________________________________________________________________

Hello World

SQL> select php_str ('<?php print abs (-1);?>');
callret
VARCHAR
_______________________________________________________________________________

1

SQL> set MACRO_SUBSTITUTION off;
SQL> select php_str ('<?php echo $a?>', 'a=Hello+World');
callret
VARCHAR
_______________________________________________________________________________

Hello World

SQL> select php_str ('<?php echo $a?>', vector ('a', 'Hello World'));
callret
VARCHAR
```

```
Hello World

SQL> select php_str ('<?php echo "$a $b"?>', 'a=Hello+World&b=Hello+Again+World');
callret
VARCHAR
_______________________________________________________________________________

Hello World Hello Again World

SQL> select php_str ('<?php $a=1; $b=2; $c=3; $d=$a+$b+$c; echo $d?>');
callret
VARCHAR
_______________________________________________________________________________

6

SQL>  select php_str ('<?php $a=8; $b=4; $c=8; echo $a|$b&$c?>');
callret
VARCHAR
_______________________________________________________________________________

8
```

Example 14.66. Examples of the php redirect page

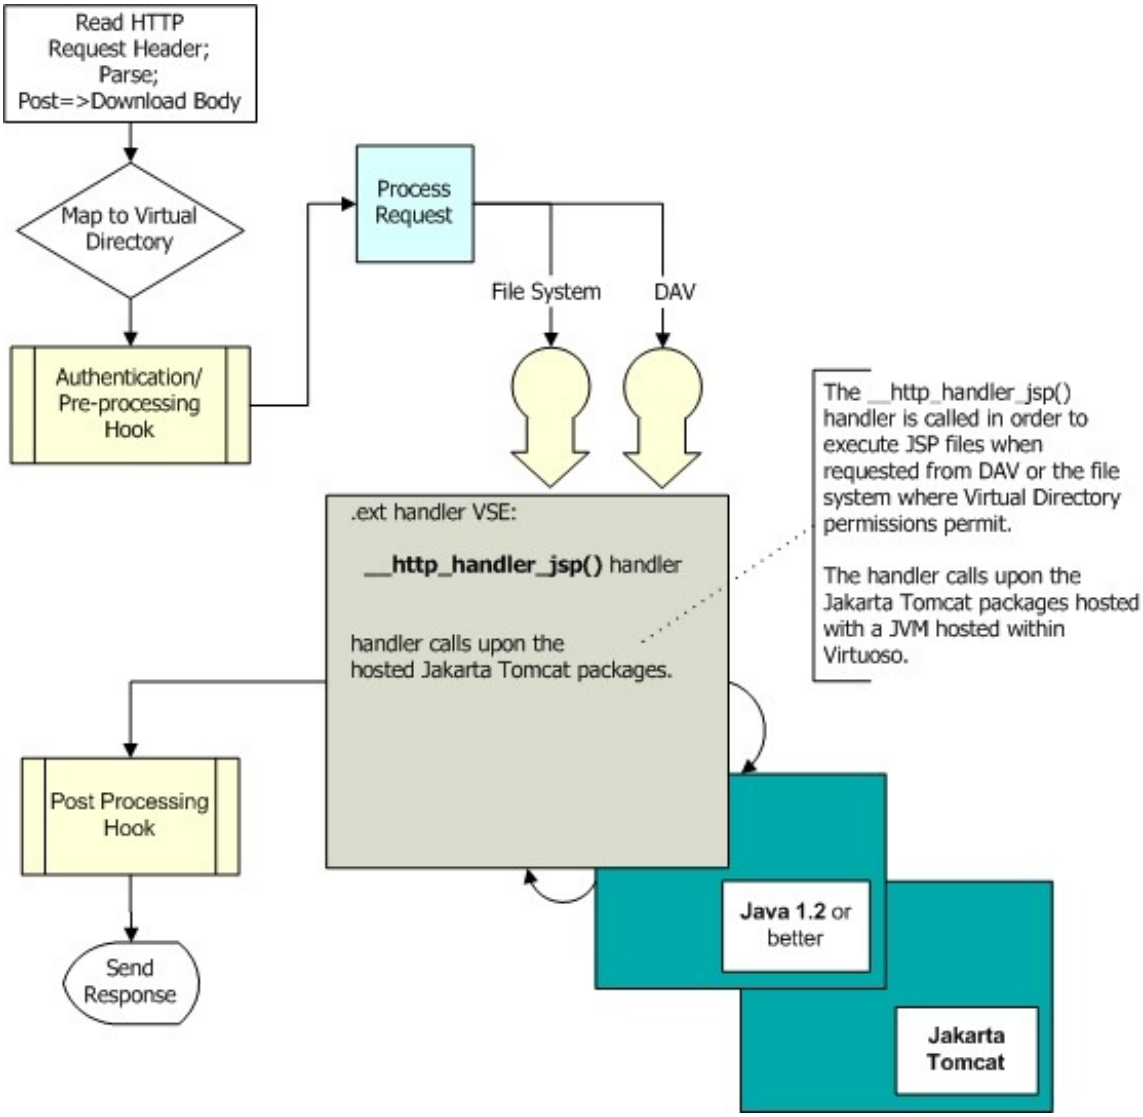
This is test how the PHP processor can instruct the HTTP server to send a custom response and header to the user agent. The following page can stored on the file system or in the WebDAV repository (in which case execution rights must be enabled). Hitting that page will redirect user-agent to the index.html page in HTTP server root.

```
<?php
  header ("HTTP/1.1 302 Found");
  header ("Location: /index.html");
?>
```

14.9. Deploying JSP Applications

The Virtuoso server with Java hosting support can be used to execute JSP pages, however, Virtuoso requires a JSP container engine first. Jakarta provide such an engine that can be hosted inside Virtuoso with Java support. This section describes how JSP's can be executed using Jakarta Tomcat JSP implementation.

Figure 14.54. The HTTP JSP handler using Jakarta Tomcat



14.9.1. Environment Setup & Verification

The following components are required:

Java SDK (or runtime only) needs to be installed. Version 1.2 or later.

Jakarta Tomcat package must be installed and configured. This can be obtained from the Jakarta project site (http://jakarta.apache.org/tomcat/)

The virtuoso.ini file must edited to including the following settings in the `[Parameters]` section:

```
.....
JavaClasspath = <jdk install dir>/lib/tools.jar:<tomcat install dir>/bin/bootstrap.jar
JavaVMOption1 = -Djava.endorsed.dirs=<tomcat install dir>/bin:<tomcat install dir>/common/endorsed
JavaVMOption2 = -Dcatalina.base=<tomcat install dir>
JavaVMOption3 = -Dcatalina.home=<tomcat install dir>
JavaVMOption4 = -Djava.io.tmpdir=<tomcat install dir>/temp
.....
```

Note:

The above has been tested for the jakarta-tomcat-4.1.18 distribution only. Setting may vary for any other versions of Jakarta Tomcat, in which case we advise you consult the Tomcat documentation.

Run the `virtuoso-*-javavm*-t` binary, The Virtuoso server that includes Java hosting.

Start the Jakarta Tomcat server inside virtuoso server process using the following command from ISQL:

```
SQL> java_call_method ('org.apache.catalina.startup.BootstrapService', null, 'main', 'V',
     vector ('[Ljava/lang/String;', vector ('start')));
```

In order to invoke the above command automatically at server startup you might put it in the autoexec.isql init script.

Make a virtual directory for accessing JSP server, here is an example:

```
vhost_define (lpath=>'/tomcat',ppath=>'http://example.com:8080/');
```

Verify that your installations are correct by pointing your web browser of choice to `http://example.com:8890/tomcat/` (assuming you are working on your local machine). Run some of JSP examples provided with Tomcat distribution to verify that they are executed without errors.

Note:
For debugging purposes you may run the virtuoso-*-javavm*-t server with foreground option to receive Java error messages, if any occur.

14.10. Perl Hosting

Virtuoso functionality can be enhanced through external libraries by loading shared objects or DLLs. The new functions are written in a language of the developer's choice and compiled to produce a shared library appropriate to the operating system. The path to the shared library must be declared in the Virtuoso INI file and the server restarted before it can be used.

The Perl language is hosted within Virtuoso in this way. hosting_perl.so is the library used.

The Virtuoso INI file uses a [Plugins] configuration section for listing shared libraries for the server to load upon startup. An example of this is:

```
[Plugins]
LoadPath = /home/virtuoso/hosting
Load1 = Hosting, hosting_perl.so
..
```

The "Hosting" type defines the entry points for initialization of the runtime hosting environment, destruction of the user environment and execution of a file or string containing commands in the hosted language. It also returns a list of file extensions that it is capable of processing. Virtuoso dynamically defines memory-resident (no disk image) HTTP server handlers for each specified type.

The Perl hosting plugin supports 'pl' extension. Hence, upon initialization of the hosting plugin, Virtuoso defines the `__http_handler_pl(..)` function according to the API for file type handlers in the Virtuoso HTTP server. With this handler in place, each hit on a .pl file (file system or WebDAV) with appropriate execute permissions will cause the HTTP server to execute the code within it and return the result instead of simply the file's contents.

The handler will call the __hosting_http_handler VSE with a special set of parameters to represent the HTTP environment correctly.

Virtuoso will normally call the plugin to memory as required, and expel it when finished. This behavior can be controlled by the INI file parameter:

```
[HTTPServer]
PersistentHostingModules = 1/0 default 0
```

Setting `PersistentHostingModules` to "1" prevents Virtuoso from removing the interpreters from the HTTP threads after each request.

See Also:
VSEI Plugins

Example 14.67. Using the Perl Plugin

Executing Perl code directly:

```
select __hosting_http_handler ('pl', 'print "hello world"; ', '', vector (), 'helloworld.pl');
```

```
returns : hello world
```

Executing a perl script file (perl/test_print.pl in the Virtuoso working directory):

```
/perl/test_print.pl
-------------------
#!/usr/bin/perl
print "hello world file";

select __hosting_http_handler ('pl', 'perl/test_print.pl');

returns : hello world file
```

Note:
The hosting_perl hosting module uses the perl `tie()` function to "tie" up the STDIN, STDOUT, STDERR, exit() and %ENV perl objects. Untying any of these may lead to unpredictable results.

14.11. Python Hosting

Virtuoso functionality can be enhanced through external libraries by loading shared objects or DLLs. The new functions are written in a language of choice and compiled to produce a shared library appropriate to the operating system. The path to the shared library must be declared in the Virtuoso INI file and the server restarted before it can be used.

The Python language is hosted within Virtuoso in this way. `hosting_python.so` (or `hosting_python.dll`) is the library used.

The Python hosting module requires the Python library, version 2.2.2 or above, to build and use the module, which then must be installed in the Plugins-Load-path defined in the Virtuoso ini file. The source code and build script (`build.py`) for building the `hosting_python.so` module are included in the Unix distribution in the `custom/hosting/python` directory. The Unix installer will offer to build it near the end of the installation process. The build.py is a kind of Makefile. On unix it requires `libtool` and `cc` in the path. On windows it requires `cl.exe` in the path.

The Virtuoso INI file uses a [Plugins] configuration section for listing shared libraries for the server to load upon startup. An example of this is:

```
[Plugins]
LoadPath = /home/virtuoso/hosting
Load1 = Hosting, hosting_python.so
..
```

The "Hosting" type defines the entry points for initialization of the runtime hosting environment, destruction of the user environment and execution of a file or string containing commands in the hosted language. It also returns a list of file extensions that it is capable of processing. Virtuoso dynamically defines memory-resident (no disk image) HTTP server handlers for each specified type.

The Python hosting plugin supports the 'py' extension. Hence, upon initialization of the hosting plugin, Virtuoso defines the `__http_handler_py(..)` function according to the API for file type handlers in the Virtuoso HTTP server. With this handler in place, each hit on a .py file (file system or WebDAV) with appropriate execute permissions will cause the HTTP server to execute the code within it and return the result instead of simple the file contents.

The python interpreter has a global lock unrelated to the Virtuoso hosting module, thus no more than one thread can run python code at a time.

The handler will call the __hosting_http_handler VSE with a special set of parameters to represent the HTTP environment correctly. Virtuoso will, by default call the plugin to memory as required, and expel it when finished. This behavior can be controlled by the INI file parameter:

```
[HTTPServer]
PersistentHostingModules = 1/0 default 0
```

Setting `PersistentHostingModules` to "1" prevents Virtuoso from removing the interpreters from the HTTP threads after each request.

See Also:
VSEI Plugins

Example 14.68. Using the Python Plugin

Executing Python code directly:

```
select __hosting_http_handler ('py', 'print "hello world"; ', '', vector (), 'helloworld.py');

returns : hello world
```

Executing a python script file (python/test_print.py in the Virtuoso working directory):

```
python/test_print.py
--------------------
#!/usr/bin/python
print "hello world file";

select __hosting_http_handler ('py', 'python/test_print.py');

returns : hello world file
```

14.12. Ruby Hosting

Virtuoso functionality can be enhanced through external libraries by loading shared objects or DLLs. The new functions are written in a language of choice and compiled to produce a shared library appropriate to the operating system. The path to the shared library must be declared in the Virtuoso INI file and the server restarted before it can be used.

The Ruby language is hosted within Virtuoso in this way. `hosting_ruby.so` (or `hosting_ruby.dll`) is the library used.

The Ruby hosting module requires the Ruby library, version 1.8.3 or above, to build and use the module, which then must be installed in the Plugins-Load-path defined in the Virtuoso ini file. The source code for building the `hosting_ruby.so` module are included in the Unix distribution in the `custom/hosting/ruby` directory. The Unix installer will offer to build it near the end of the installation process.

The Virtuoso INI file uses a [Plugins] configuration section for listing shared libraries for the server to load upon startup. An example of this is:

```
[Plugins]
LoadPath = /home/virtuoso/hosting
Load1 = Hosting, hosting_ruby.so
..
```

The "Hosting" type defines the entry points for initialization of the runtime hosting environment, destruction of the user environment and execution of a file or string containing commands in the hosted language. It also returns a list of file extensions that it is capable of processing. Virtuoso dynamically defines memory-resident (no disk image) HTTP server handlers for each specified type.

The Ruby hosting plugin supports the 'rb' extension. Hence, upon initialization of the hosting plugin, Virtuoso defines the `__http_handler_rb(..)` function according to the API for file type handlers in the Virtuoso HTTP server. With this handler in place, each hit on a .rb file (file system or WebDAV) with appropriate execute permissions will cause the HTTP server to execute the code within it and return the result instead of simple the file contents.

The ruby interpreter has a global lock unrelated to the Virtuoso hosting module, thus no more than one thread can run ruby code at a time.

The handler will call the __hosting_http_handler VSE with a special set of parameters to represent the HTTP environment correctly. Virtuoso will, by default call the plugin to memory as required, and expel it when finished. This behavior can be controlled by the INI file parameter:

```
[HTTPServer]
PersistentHostingModules = 1/0 default 0
```

Setting `PersistentHostingModules` to "1" prevents Virtuoso from removing the interpreters from the HTTP threads after each request.

Example 14.69. Using the Ruby Plugin

Executing Ruby code directly:

```
select __hosting_http_handler ('rb', 'print "hello world"; ', '', vector (), 'helloworld.rb');

returns : hello world
```

Executing a ruby script file (ruby/test_print.rb in the Virtuoso working directory):

```
ruby/test_print.rb
-------------------
#!/usr/bin/ruby
print "hello world file";

select __hosting_http_handler ('rb', 'ruby/test_print.rb');

returns : hello world file
```

Chapter 15. XML Support

Abstract

This chapter covers Virtuoso's XML, full text retrieval and related functions.

Virtuoso provides free text indexing capabilities for textual data, including XML data. Virtuoso supports extraction of XML documents from SQL datasets. It also supports XPath , XQuery , XSLT and XML Schema validation.

An SQL long varchar, long xml or xmltype column in a database table can contain XML data as text or in a binary serialized format, respectively. If a column value is a well-formed XML fragment there are special operations that can be performed on the value. There is an SQL data type that represents an XML entity. A string representing a well-formed XML entity can be converted into an entity object representing the root node. XPath expressions can then be applied to the entity in order to retrieve other entities or sets of entities. Returning an XML entity to a client application or printing it out on a dynamic web page will produce the text representation of the entity, complete with start and end tags, attributes, namespaces, and so forth.

An entity object can be stored as a value of a long varchar or varchar column. This will produce and store the text corresponding to the entity. Storing the same into a long xml or xmltype column will provide a more compact representation and will guarantee well-formedness and optionally schema validity, even if the data comes in as text.

A long varchar column can contain huge XML documents as special "persistent XML entity" objects. XML entities of this sort consume only a little amount of memory and load small portions of data from disk to memory on demand; an application can handle XML documents that are order of magnitude larger than the amount of available memory. LONG XML column type is convenient if a column contains only valid XML documents. An application can save XML entities to LONG XML columns and retrieve them back without calling any type conversion functions. A special user-defined type XMLType allows the use of an XML entity as a base for deriving user-defined types from it.

The `xpath_contains` SQL predicate can be used to test whether a column value matches a given XPath expression. If the XPath expression specifies a node set and that set is non-empty for a given column value, it is possible to bind a result variable to each element of the set. In this way a single row of data in a table can produce multiple rows in an SQL result set, one for each entity selected by the XPath predicate.

If there is a free text index on a column it is possible to define that the content be checked for well-formedness. In this case both `contains` and `xpath_contains` predicates can be applied to the same column in the same query. You should create a free text index on your XML data if you expect any content-based searches. The free text index will recognize specific features of XML and allow their use in searches.

The `xcontains` SQL predicate is a combination of XPath and free text, making automatic use of the free text index for evaluating an XPath expression. This predicate also allows you to test text values of entities for complex free text conditions such as proximity.

There is a user interface for using this feature on DAV resources. The use of the `xpath_contains` predicate is not limited to DAV resources though. The use of XPath with XML values is independent of free text indexing and of XML views.

Virtuoso offers functions for XPath processing of well-formed XML strings in SQL. Together with the Virtuoso free text support, these functions offer a powerful free-form and structured content retrieval system. You can search for XPath matches in any XML-populated column. One practical example would be the RES_CONTENT column of the WS.WS.SYS_DAV_RES table, which contains the contents of documents stored in the WebDAV repository. As with the sample database, which contains the XML sources for this documentation, you may store XML documents directly in the WebDAV repository.

An SQL statement can return complex XML documents based on relational data. Virtuoso supports both Microsoft's "FOR XML" syntax and the standard set of SQLX XML composing functions like `XMLELEMENT` and `XMLAGG` . Very complicated processing can be done in a single statement that combines XML composing functions, `xquery_eval` and `xslt` .

Virtuoso/PL routines can modify XML entities in DOM style (functions like `XMLAppendChildren` and `XMLReplace`). Doing local changes this way can be simpler than via XSLT or XQuery; DOM modifications also help speed-critical applications to avoid unnecessary copying of data.

Virtuoso's XML parser can read XML documents of any complexity. It can validate source documents against DTD and XML schema, load compound documents or their fragments, recover from errors in ill-formed HTML documents like popular browsers

can.

15.1. Rendering SQL Queries as XML (FOR XML Clause)

Virtuoso extends SQL-92 with the FOR XML clause that allows any SQL result set to be turned into XML according to some simple rules. The notation and functionality are similar to those offered by Microsoft SQL Server and IIS.

The FOR XML clause has 3 variants:

RAW. Make an XML entity from each row of the result set; do not attempt to construct hierarchies. Each row's data is enclosed in a <ROW/> element and each column is either an attribute or child element.

AUTO. A hierarchy is constructed with one level for each table of the join for which at least one column is selected. The table whose column is first mentioned in the selection will be the topmost element, the next table its child, etc. Each level of the tree will consist of one type of element. A parent element will have multiple children if consecutive rows do not differ in the column values coming from the parent element. When a table's column values differ from the previous row, the element and all children thereof are closed and a new element is started, with children filled out from other columns of the result set.

EXPLICIT. This mode gives more control on the resulting tree's structure while requiring a more elaborate query structure. In this mode, the query will be a UNION ALL of many joins and each row will specify exactly one element. Which type of element this is and where in the tree it will be placed are determined by the values of the first two columns, TAG and PARENT.

In all modes, columns may either be attributes or sub-elements. The *ELEMENT* keyword after the FOR XML clause forces all columns to be rendered as sub-elements; attribute are the default.

In all modes except explicit, the names of elements are the unprefixed table names and the names of attributes are the columns' names in the result set. If tables have correlation names the correlation names are used in the output instead of the table names. Expressions are allowed in the selections but these should be named using AS. In AUTO mode Virtuoso assumes expressions belong to the topmost element.

The FOR XML clause is generally allowed in SELECT statements in place of the FOR UPDATE clause. However it only has an effect when the statement is executed through the `xml_auto()` function.

See Also:

The SQL-XML Statements page described in the Visual Server Administration Interface section provides a fast graphical way of supplying an SQL statement to Virtuoso and saving the view as a resource accessible from the WebDAV store.

15.1.1. FOR XML EXPLICIT Mode

This mode gives the developer the most control over the generated result tree but requires a verbose query formulation. Each row must begin with two integer columns, the first identifying the element represented by the row and the second the parent element type of this element. Consider:

```
select 1 as tag, null as parent,
       "CategoryID" as [category!1!cid],
       "CategoryName" as [category!1!name],
       NULL as [product!2!pid],
       NULL as [product!2!name!element]
from "Demo".."Categories"
union all
select 2, 1, "category" ."CategoryID", NULL, "ProductID", "ProductName"
    from "Demo".."Categories" "category", "Demo".."Products" as "product"
    where "product"."CategoryID" = "category"."CategoryID"
order by [category!1!cid], 5
for xml explicit;
```

This query makes a two level tree where Categories have Product children. The selection in the first UNION term specifies the element types in the result set. The two first columns, TAG and PARENT are required in all EXPLICIT queries. Subsequent columns have an extended AS declaration that specifies which element they belong to, what that element is called in XML and what the column will be called. A row where TAG has a value of 1 will pick the columns which has [xxx!1!yyy] as their alias; rows with a TAG of 2 will pick columns with an alias with [xxx!2!yyy] and so on.

If consecutive rows have a different TAG but the same PARENT, these will be siblings of different types. This possibility does not exist with the other FOR XML modes.

If the PARENT is 0 or NULL, then any previously open elements in the result are closed and the element of the row becomes a top-level element. When PARENT refers to the TAG of a presently open element in the set, all children of that element are closed and the row's element is inserted as the next child of the last element with the TAG equal to the new row's PARENT. All open tags are closed at the end of the result set.

Note

Since each level of the tree is generated by a different term in the UNION ALL, an ORDER BY will invariably be needed to group the children after their parents. If the parent rows have NULLs in place of the child row's key values, the parent gets sorted first because NULL collates first.

15.1.2. Examples of FOR XML

This section gives one example of each mode of FOR XML combined with the `xml_auto()` function to help us display the results simply. First we create a procedure that enables us to supply SQL and return XML using the `xml_auto()` function.

```
create procedure xmla (in q varchar)
{
  declare st any;
  st := string_output ();
  xml_auto (q, vector (), st);
  result_names (q);
  result (string_output_string (st));
}
```

Now we can apply this to a couple of examples:

Example 15.1. XML RAW

```
xmla ('select "category"."CategoryID", "CategoryName",
    "ProductName", "ProductID"
    from "Demo".."Categories" "category", "Demo".."Products" as "product"
    where "product"."CategoryID" = "category"."CategoryID" FOR XML RAW');

<ROW CategoryID="1" CategoryName="Beverages" ProductName="Chai" ProductID="1">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Chang" ProductID="2">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Guaraná Fantástica" ProductID="24">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Sasquatch Ale" ProductID="34">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Steeleye Stout" ProductID="35">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Côte de Blaye" ProductID="38">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Chartreuse verte" ProductID="39">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Ipoh Coffee" ProductID="43">
</ROW>
<ROW CategoryID="1" CategoryName="Beverages" ProductName="Laughing Lumberjack Lager" ProductID="67">
</ROW>
.....
```

As we can see, RAW mode produces a simple row-by-row account of the data encased within the <ROW.../> tags. This is the simplest mode.

Example 15.2. XML AUTO

```
xmla ('select "category"."CategoryID", "CategoryName",
    "ProductName", "ProductID"
    from "Demo".."Categories" "category", "Demo".."Products" as "product"
    where "product"."CategoryID" = "category"."CategoryID" FOR XML AUTO ELEMENT');

<category>
 <CategoryID>1</CategoryID> <CategoryName>Beverages</CategoryName><product>
 <ProductName>Chai</ProductName> <ProductID>1</ProductID></product>
```

```
<product>
 <ProductName>Chang</ProductName> <ProductID>2</ProductID></product>
<product>
 <ProductName>Guaraná Fantástica</ProductName> <ProductID>24</ProductID></product>
<product>
 <ProductName>Sasquatch Ale</ProductName> <ProductID>34</ProductID></product>
<product>
 <ProductName>Steeleye Stout</ProductName> <ProductID>35</ProductID></product>
<product>
 <ProductName>Côte de Blaye</ProductName> <ProductID>38</ProductID></product>
<product>
 <ProductName>Chartreuse verte</ProductName> <ProductID>39</ProductID></product>
<product>
 <ProductName>Ipoh Coffee</ProductName> <ProductID>43</ProductID></product>
<product>
 <ProductName>Laughing Lumberjack Lager</ProductName> <ProductID>67</ProductID></product>
<product>
.....
```

In contrast to RAW mode, AUTO produces results that are more tree-like. Only one category element is used for each category, and that contains all the children of the category.

Example 15.3. XML EXPLICIT

```
xmla ('
select 1 as tag, null as parent,
       "CategoryID" as [category!1!cid],
       "CategoryName" as [category!1!name],
       NULL as [product!2!pid],
       NULL as [product!2!name!element]
from "Demo".."Categories"
union all
select 2, 1, "category" ."CategoryID", NULL, "ProductID", "ProductName"
    from "Demo".."Categories" "category", "Demo".."Products" as "product"
    where "product"."CategoryID" = "category"."CategoryID"
order by [category!1!cid], 5
FOR XML EXPLICIT');

<CATEGORY CID="1" NAME="Beverages">
<PRODUCT PID="1">
 <NAME>Chai</NAME></PRODUCT>
<PRODUCT PID="2">
 <NAME>Chang</NAME></PRODUCT>
<PRODUCT PID="24">
 <NAME>Guaraná Fantástica</NAME></PRODUCT>
<PRODUCT PID="34">
 <NAME>Sasquatch Ale</NAME></PRODUCT>
<PRODUCT PID="35">
 <NAME>Steeleye Stout</NAME></PRODUCT>
<PRODUCT PID="38">
 <NAME>Côte de Blaye</NAME></PRODUCT>
<PRODUCT PID="39">
 <NAME>Chartreuse verte</NAME></PRODUCT>
<PRODUCT PID="43">
 <NAME>Ipoh Coffee</NAME></PRODUCT>
<PRODUCT PID="67">
 <NAME>Laughing Lumberjack Lager</NAME></PRODUCT>
<PRODUCT PID="70">
 <NAME>Outback Lager</NAME></PRODUCT>
<PRODUCT PID="75">
 <NAME>Rhönbräu Klosterbier</NAME></PRODUCT>
<PRODUCT PID="76">
 <NAME>Lakkalikööri</NAME></PRODUCT>
</CATEGORY>
<CATEGORY CID="2" NAME="Condiments">
<PRODUCT PID="3">
.....
```

In this example, we specify precisely the tree structure we wish, and construct the EXPLICIT query to produce that tree. Many times programmers know what the resulting XML should look like but do not know how to get exactly what they want. FOR XML EXPLICIT can be very useful in these cases.

15.1.3. Functions

`xml_auto()`

15.1.4. FOR XML Syntax

```
for__xml ::= FOR XML <mode> [ ELEMENT ]

<mode> ::= RAW | AUTO | EXPLICIT

<explicit column> ::=  scalar_exp AS '[' <element> '!' <tag no> '!'
                    <column name> [ '!' <option> ] ']'

<tag no> ::= INTNUM

<column name> ::= IDENTIFIER

<element> ::= IDENTIFIER

<option> ::= IDENTIFIER
```

The <explicit column> should be used in the selection list of the first term of the UNION ALL construct in a FOR XML EXPLICIT query. Virtuoso provides this functionality separately from any Web server context, although these are principally expected to be used inside VSP pages.

The text of <option> part of the <explicit column> is ignored but if it is present then the value is placed into a sub-element of the element for the row, not into an attribute.

15.2. XML Composing Functions in SQL Statements (SQLX)

The preferred means of constructing XML data from SQL is to use the standard SQLX SQL extension.

SQLX is a collection of functions added for creating XML entities from standard relational queries. Basically, you write a SQL statement with calls to SQLX functions in the selection and a piece of XML is created.

There are five XML composing functions:

`XMLELEMENT()` creates a single XML element that can contain an arbitrary number of attributes and sub-elements.

`XMLATTRIBUTES()` lists XML attributes to be placed in the XML element created by an enclosing call of `XMLELEMENT()` .

`XMLCONCAT()` returns a forest of XML values by concatenating a list of XML values or forests.

`XMLAGG()` is an aggregate function that creates a forest of XML values by concatenating the XML values that are returned from multiple rows.

`XMLFOREST()` is similar to `XMLATTRIBUTES()` but returns a forest of elements instead of list of attributes.

These functions belong to the SQLX standard, an emerging SQL standard for XML. All the functions take a variable number of arguments.

`XMLELEMENT` is used to construct XML elements from relational data. It takes as parameters the element name, an optional collection of attributes for the element (returned by `XMLATTRIBUTES` call), column names, strings, `XMLELEMENT` , `XMLFOREST` , `XMLCONCAT` , and `XMLAGG` calls, and an entity objects (returned by corresponding functions, e.g. `xtree_doc` , `xpath_eval` , `xquery_eval`) which will make up the content of the element (an exception from this is an attribute entity returned by `xquery_eval` - in this case it is joined to the list of the element's attributes). Column names, strings and attribute entities returned by `xpath_eval` will make up the text content of the element. The others will make up the children of the element.

In the `XMLATTRIBUTES` clause, the value expressions are evaluated to get the values for the attributes.

XMLFOREST produces a forest of XML elements from a given list of arguments. It accepts a list of SQL value expressions as its arguments, and produces an XML element from each value returned.

XMLCONCAT produces a forest of elements by concatenating a list of XML values. XMLCONCAT accepts a list of XML value expressions as its arguments, and produces a forest of elements by concatenating the XML values that are returned from the same row to make one value. If an argument of the XMLCONCAT is an entity object returned by xquery_eval or path_eval , it must not be an attribute.

The following statements create the same result sets:

```
select XMLELEMENT ('Person',
                        XMLELEMENT ('firstname', "FirstName"),
                        XMLELEMENT ('lastname', "LastName"),
                        xquery_eval('//country', xtree_doc('<a><country>USA</country></a>')))
from "Demo"."demo"."Employees";

select
      XMLELEMENT ('Person',
                        XMLFOREST ("FirstName"as "firstname", "LastName" as "lastname"),
                        xquery_eval('//country', xtree_doc('<a><country>USA</country></a>')))
from "Demo"."demo"."Employees";

select
      XMLELEMENT ('Person',
                              XMLCONCAT (
                                        XMLELEMENT ('firstname', "FirstName"),
                                        XMLELEMENT ('lastname', "LastName"),
                                        xquery_eval('//country', xtree_doc('<a><country>USA</country></a>
from "Demo"."demo"."Employees";
```

Note:
The second statement is more effective than the others.

In order to return more than one row of values, you can use XMLAGG . XMLAGG is an aggregate function that produces a forest of XML elements from a collection of XML elements. It concatenates the values returned from one column of multiple rows, unlike XMLCONCAT, which concatenates the values returned from multiple columns in the same row.

The parameters that would be used as element names (in the XMLELEMENT and in the 'AS clause ' of the XMLFOREST and XMLATTRIBUTES) must be valid XML names. If the 'AS clause ' is absent in a list of the parameters of the XMLFOREST or XMLATTRIBUTES , Virtuoso uses the partially escaped form of the column name as the element or attribute name. The partially escaped form means that SQL <identifier> characters that are valid characters in a XML NAME are not changed, SQL <identifier> character that is not valid XML NAME character is replaced with "_xHHHH_", where HHHH is character's upper case hexadecimal code. For example, "first_name" is replaced with "first_x005F_name", "last name" is replaced with "last_x0020_name".

The following example creates an 'FullAddress' element with

- four attributes, three of them ('PostalCode', 'Address', 'City') are produced by XMLATTRIBUTES, and the fourth attribute - 'country' is calculated by xquery_eval
- 'Region' subelement, that is produced by xtree_doc
- text content, that is produced by xpath_eval
- 'emp' subelement with text content from the column "LastName", that is created by nestedXMLELEMENT

```
select XMLELEMENT ('FullAddress',
                        XMLATTRIBUTES ( "PostalCode", "Address", "City"),
                        xtree_doc ('<Region>WA</Region>'),
                        xquery_eval('//@country', xtree_doc('<a country="USA"/>')),
                        xpath_eval('//@Phone', xtree_doc('<a Phone="(206) 555-9857"/>')),
                        XMLELEMENT('emp', "LastName"))
from "Demo"."demo"."Employees"

----------------------------

   <FullAddress PostalCode="98122" Address="507 - 20th Ave. E. Apt. 2A" City="Seattle" country="USA">
        <Region>WA</Region>
        (206) 555-9857
        <emp>Davolio</emp>
```

```
  </FullAddress>
  <FullAddress PostalCode="98401" Address="908 W. Capital Way" City="Tacoma" country="USA">
      <Region>WA</Region>
      (206) 555-9857
      <emp>Fuller</emp>
  </FullAddress>
. . .
```

XMLCONCAT()

XMLELEMENT()

XMLFOREST()

XML composing functions deal with arguments of arbitrary type, but the result is always an XML entity that can contain only elements and strings. Hence there is a set of type casting rules. These rules are quite common for any XML DOM model, so they're similar to those listed for DOM function arguments :

If an instance of XMLType is passed then its internal XML entity is used.

If an array representation of an XML tree entity is passed then it is used exactly like XML entity.

If an argument is NULL then it is fully ignored, as if there is no such argument at all.

If an argument is not of a type listed above and not a string then it is cast to a string first.

A root node of some document (or of some generic XML entity) can not appear in the middle of the resulting tree. So if a root node is passed then all child nodes of the root (i.e. every top-level node of the document) will be added.

SQL/XML standards introduce a special name "forest of XML elements" for an ordered list of XML elements, like one returned by `XMLFOREST()` . In Virtuoso, forest can contain XML nodes of any sort, not only XML elements, so it can also contain strings, processing instructions and comments. Virtuoso processes any non-empty "forest" as if it were the root node of a "generic XML entity", and items of the forest were top-level nodes of that entity. Hence, a forest can be passed to any function that accepts an value of type "XML entity". The only potential problem is that this entity is well-formed if and only if the forest is non-empty. If an empty forest is serialized to an XML text then the result is an empty string that is not an acceptable input for an XML parser.

It is important to remember that the XML document can not contain two neighbour text nodes and that the text node can not be an empty string. If two consequent strings appear in the list of values of a forest or in the list of children of an new element then they are replaced with a single node that is a concatenation of these string. Similarly, if an empty string appears in the list of values of a forest or in the list of children of an new element then it is removed from the list.

15.3. Virtuoso XML Services

15.3.1. XPATH Implementation and SQL

Virtuoso offers XPATH as a query language for XML views. The statement is there converted into SQL in the context of the mapping defined by the __view XPATH option, which is mandatory. An XPATH query string is a valid top level SQL statement. This is interpreted as a single select or union of selects with the result columns being specified by various XPATH options.

The basic query string

```
XPATH [__view "cat"]/category
```

will select any top level category elements from the cat XML view, defined with CREATE XML VIEW. This has a single result column with the serialization string of the selected entity as value. This string starts with the category start tag and ends with the corresponding end tag. As many result rows are generated as there are top level category nodes in the view.

This basic behaviour can be modified by XPATH options enclosed in brackets after the XPATH keyword. These options allow specifying the output columns of the generated select statement.

15.3.2. XPATH Query Options

```
<xp option> ::=
    __* | __http | __key   | __view NAME | __tag NAME | __quiet | __base_uri STRING |
    xmlns:NAME '=' STRING | xmlns '=' STRING |
    __lang STRING | __enc STRING | KEYWORD '=' KEYWORD

<option list> ::=  | <option list> '[' <option> [...] ']'
```

The option list may occur between the XPATH keyword and the start of the path, e.g.

```
XPATH [__key __view "cat"] /category
```

The effects of the options are as follows:

__http. Send the serialization of the result entities to the HTTP client. This may only be used inside a VSP page context.

__key. Select the key of the selected entities instead of the serialization text.

__*. Select all columns of the selected entity instead of its serialization text. This is only valid when __view is specified and the result set is homogeneous.

__view STRING. Specify that the query be interpreted in the context of the specified CREATE XML VIEW, directly accessing the tables. This is mandatory since the elements referenced can only be mapped to tables in the context of an XML view.

__quiet. Specify that the query should not signal non-fatal errors. This option is for cases when an incomplete result is anyway better than nothing. Typical example is search in the collection of documents where not all documents are valid.

__base_uri STRING. Specify the base URI that can be used to resolve relative URIs in calls of XPATH functions `processXQuery()` , `processXSLT()` and `processXSLT()` . This is similar to the effect of "declare base-uri" in XQuery.

xmlns:NAME '=' STRING. This declares a pair of namespace prefix and namespace URI for use in the query expression, e.g. xmlns:xs="http://www.w3.org/2001/XMLSchema" or xmlns:ora="http://schemas.oracle.com/xpath/extension"

xmlns '=' STRING. This declares the default namespace URI for use in the query expression, e.g. xmlns="http://www.example.com/my-schema". This namespace will become both default element namespace and default function namespace.

__lang STRING. This declares the language that is used for text search expressions. This is for internationalization purposes only. See subsection "Adding New Languages And Encodings Into Virtuoso" for more details.

__enc STRING. This declares encoding of strings that are used for text search expressions. This is for internationalization purposes only. See subsections "Encoding in XPath Expressions" and "Adding New Languages And Encodings Into Virtuoso" for more details.

KEYWORD '=' KEYWORD. This is useful only if the expression uses XPATH functions like `document()` or `doc()` or if the XPATH expression is an argument of `xpath_contains` or similar special SQL predicate. These are configuration options that XPATH processor provides to the XML parser when the processor should read a document. Section "Configuration Options of the DTD Validator" lists all supported options.

15.3.3. XML Views - Representing SQL Data as Dynamic and Persistent XML

The XML view mechanism allows generating XML content from relational data and to query relational data as if it were XML without first converting it to XML.

CREATE XML VIEW statement

```
<xml view> ::=
     CREATE XML VIEW <name> as [ <namespaces_def> ] <element list> <opt_public>
```

```
<xml view> ::=
     CREATE XML VIEW <name> as [ <namespaces_def> ] <query spec> [ELEMENT] <opt_public>

<namespaces_def> ::= '[' <id_namespace> '='( name | <path string> ) [ ...]  ']'

<element list> ::= <element> [, ...]*

<element> ::=
         <table> <correlation name> AS [ <id_namespace> ':' ] <element> <columns>
         [ ON '('  <search condition> ')']
        [primary key '(' column_commalist ')' ]
        [ELEMENT]
         [ '{' <element list>'}' ]

<opt_public> ::=  PUBLIC <path string> OWNER <DAV owner name> [PERSISTENT] [INTERVAL <minutes>]

<columns> ::= '(' <column> [, ...] ')'

<column> ::=   <column name> | <column name> AS [ <id_namespace> ':' ] <attribute name>

<id_namespace> :: = identifier
```

The XML view declaration establishes a 'virtual document' a context within which XML hierarchy relationships can be translated into arbitrary joins. The virtual document can be then materialized into an actual set of persistent XML elements or used to generate SQL from XPATH.

Each table in the declaration generates an element into the result document. SQL views can be used as tables to accommodate for hidden joins, sub-queries, ordering and aggregates. If a view is used, which by nature has no primary key, the primary key clause should be used to define a uniquely identifying set of view columns.

The only restriction on the XML view declaration is that each branch has a fixed depth.

The structure of joins used to make the text can be specified in two ways: As a SQL query specification, that is a SELECT from a list of tables with a WHERE clause specifying the joins, or as a tree of join elements. The first form is called automatic and the second is called explicit. The automatic form allows generating a tree with as many levels as there are tables in the join, with elements derived from the rows at each level occupying each level of the hierarchy

With both forms the columns of the tables are mapped into either attributes or child elements of the element representing each row. In the explicit mode, the attribute / element choice can be made for each table, in the automatic mode for the entire view. The explicit mode also allows specifying a different element / attribute name whereas the automatic mode takes the name from the column name. Even if the columns are presented as child elements in the output text, they should be referenced as attributes in XPATH queries evaluated in the context of the view.

An XML namespaces can be used in XML view with two restrictions - all namespace names must be different and the first three letters of namespace name must not be 'xml', except for default namespace with name 'xmlns'.

Explicit XML Views

In the explicit form each level of the hierarchy is declared as a list of child elements. Each such element maps one table or view into an entity according to a join condition. The join conditions can reference columns from the associated table and columns from tables in parent elements. The join condition can also have scalar filtering conditions. A top element's join condition may only specify scalar conditions.

Each set of sibling child nodes is delimited by braces {}. The top level of the view typically consists of one element in the outermost braces. This element has itself a child list delimited by braces. Each such list can have more than one different element.

Each element specifies:

- SQL table
- Correlation name for use in subsequent joins for this table
- XML element name to use for delimiting a row of this table
- List of columns, with optional XML element or attribute names
- join condition - will relate rows of this table to rows of the table in the enclosing element. If this element is at the top level, this can only consist of scalar conditions

- Optional PRIMARY KEY clause, needed if the table in this element is a view, does not have a primary key or if a non-primary key unique identity is desired
- Optional ELEMENT flag
- Optional list of child elements, delimited by braces

Note:

A correlation name is mandatory for all the tables.

The column list can mention a single column or a single column renamed into an XML attribute of a different name. If a column of a table is referenced in a subsequent join condition it must appear in the output columns list. Expressions are not directly allowed but a view with expression columns can be used.

The opt_public clause, when present, offers a shorthand for calling xml_view_publish at the same time as making the definition. This makes a DAV resource reflecting the contents of the view. The contents may either be generated on demand or persisted as a DAV accessible XML document. In the latter case the document may be regenerated at a fixed interval. The interval is expressed in minutes.

The path is expressed as an absolute path from the root collection of the DAV server.

Note:

This root collection may be mapped into various places in the web server's URL space.

```
create xml view xx ... public '/xx.xml' owner 'dav' persistent interval 1;
```

is equivalent to:

```
create xml view xx ...;
xml_view_publish (xx, /xx.xml', 'dav', 1, 1);
```

A DAV resource created in this manner can be deleted as any DAV resource. The XML view itself is not affected but a possibly existing refresh job will be automatically deleted.

One XML view can be published several times with different names and owners. There may also exist persistent and non-persistent publications of the same view.

The CREATE XML VIEW statement defines stored procedures for generating an XML text fragment corresponding to each element declared in the view.

The names of the procedures are composed as follows:

```
create procedure http_view_<view name>
        (inout output_mode)

create procedure http_<view name>_<element name>_<correlation name>
        (in pk1 any, ..., in output_mode integer)
```

An http output procedure is created for each <element> in the create xml view declaration. It takes the primary key columns of the table in question in key order plus a mode flag. It then outputs the serialization of the specified element and any child elements. For an output mode of 0 the result goes directly to an HTTP client. For an output_mode of 1 the procedure returns the serialization as a string. Note that for this to work the tables in question must be real tables and the join conditions must only reference the next higher table in the create xml view tree. Further, the primary key columns of each table should be mentioned in the columns list for that table along with any foreign keys referenced in subsequent join conditions.

Example 15.4. Examples

```
create xml view "cat" as
{
  "Demo"."demo"."Categories" "C" as "category"
        ("CategoryID", "Description" as "description")
    {
      "Demo"."demo"."Products" "P" as "product"  ("ProductName")
        on ("P"."CategoryID" = "C"."CategoryID")
    }
}
```

This declares a two level hierarchy with a category node for each category and a product child node for each product in the category.

```
create xml view "cats_e" as
  select "category"."CategoryID", "CategoryName",
    "ProductName", "ProductID"
    from "Demo".."Categories" "category", "Demo".."Products" as "product"
    where "product"."CategoryID" = "category"."CategoryID" element;
```

Here is a similar example, this time using the element option.

The procedures are

```
xmlg_cat
http_cat_category_C (in categoryid any, in _out integer);
http_cat_product_P (in productid any, in _out integer);
```

In the following example the function returns the selected items as an XML fragment. Consecutive elements are separated by new-lines for readability.

Example 15.5. Example

```
SQL> call "http_cat_category_C" (1, 1);

1 sets? Done. -- 5 msec.
RESULT=
<category CategoryID="1" description="Soft drinks, coffees, teas, beers, and ales" >
<product ProductName="Chai" ></product>
<product ProductName="Chang" ></product>
<product ProductName="Guarana Fantastica" ></product>
<product ProductName="Sasquatch Ale" ></product>
<product ProductName="Steeleye Stout" ></product>
<product ProductName="Côte de Blaye" ></product>
<product ProductName="Chartreuse verte" ></product>
<product ProductName="Ipoh Coffee" ></product>
<product ProductName="Laughing Lumberjack Lager" ></product>
<product ProductName="Outback Lager" ></product>
<product ProductName="Rhönbrooou Klosterbier" ></product>
<product ProductName="Lakkalikööri" ></product>
</category>
```

The below example shows how to use a SQL view for hiding a join. The below view generates for each table a set of column children and a set of index children, which in turn have column children.

```
create view KEY_COLS as select KP_KEY_ID, KP_NTH, C.*
        from SYS_KEY_PARTS, SYS_COLS C where COL_ID = KP_COL;

create xml view "schema" as
{
  DB.DBA.SYS_KEYS k as "table" ("KEY_TABLE" as "name",
        KEY_ID as "key_id", KEY_TABLE as "table")
        on (k.KEY_IS_MAIN = 1 and k.KEY_MIGRATE_TO is null)
        { DB.DBA.KEY_COLS  c as "column" (COLUMN as name)
                on (k.KEY_ID = c.KP_KEY_ID)
                primary key (COL_ID),
        DB.DBA.SYS_KEYS i as "index" (KEY_NAME
          as "name", KEY_ID as "key_id", KEY_N_SIGNIFICANT as "n_parts")
          on (i.KEY_TABLE = k.KEY_TABLE and i.KEY_IS_MAIN = 0 and i.KEY_MIGRATE_TO is null)
          {
            DB.DBA.KEY_COLS ic as "column" (COLUMN as "name")
              on (ic.KP_NTH < i.KEY_N_SIGNIFICANT and ic.KP_KEY_ID = i.KEY_ID)
              primary key (COL_ID)
              }
        }
};
```

The following query will return the subtree describing the Customers table in the demo database:

```
XPATH [__view 'schema']
        /table[@name = 'Demo.demo.Customers'];

<table name="0" key_id="1011" table="Demo.demo.Customers" >
<column name="CustomerID" ></column>
<column name="CompanyName" ></column>
<column name="ContactName" ></column>
<column name="ContactTitle" ></column>
<column name="Address" ></column>
<column name="City" ></column>
<column name="Region" ></column>
<column name="PostalCode" ></column>
<column name="Country" ></column>
<column name="Phone" ></column>
<column name="Fax" ></column>
<index name="City" key_id="1012" n_parts="2" >
<column name="City" ></column>
<column name="CustomerID" ></column>
</index>
<index name="CompanyName2" key_id="1013" n_parts="2" >
<column name="CompanyName" ></column>
<column name="CustomerID" ></column>
</index>
<index name="PostalCode2" key_id="1014" n_parts="2" >
<column name="PostalCode" ></column>
<column name="CustomerID" ></column>
</index>
<index name="Region" key_id="1015" n_parts="2" >
<column name="Region" ></column>
<column name="CustomerID" ></column>
</index>
</table>
```

Automatic XML Views - Creating XML Views from SELECT Statements

The automatic form of CREATE XML VIEW will take a select statement and infer a hierarchy from it, based on the order of tables in the from clause. The parent table should be to the left of its children. This is practical if the tables form a hierarchy in application terms, like orders and order lines or departments and employees. This notation allows arbitrary depth but all siblings at the same level will be of the same type. Elements of child rows will be child elements of the element of their parent row, where the join condition identifies the child rows for one parent row.

The columns in the selection will appear as attributes or child elements of the rows selected. The names of the attributes will be the names of the columns. The names of the siblings will be the names of the tables in the from clause, without qualifiers or owners. Expressions should not appear in the selection. If the use of expressions is required then you may create a SQL view first to facilitate this.

The ELEMENT keyword may be present at the end of the select, before the publishing keywords. This will cause all columns to be represented as child elements of the element corresponding to the row. Note that even if the element switch is present, the values will appear like attributes in an XPATH query inside the view.

Note

SQL views or derived tables may not appear directly in the select. The reason for this is that a procedure is generated for each level of the generated XML tree and that this must take unique identifying column values for the element in question. If one desires to use a view, the explicit form should be used, with the primary key option specified where appropriate.

Add to text for explicit XML views

Each set of sibling child nodes is delimited by braces {}. The top level of the view typically consists of one element in the outermost braces. This element has itself a child list delimited by braces. Each such list can have more than one different element.

Each element specifies:

- SQL table
- Correlation name for use in subsequent joins for this table

- XML element name to use for delimiting a row of this table
- List of columns, with optional XML element or attribute names
- join condition - will relate rows of this table to rows of the table in the enclosing element. If this element is at the top level, this can only consist of scalar conditions
- Optional PRIMARY KEY clause, needed if the table in this element is a view, does not have a primary key or if a non-primary key unique identity is desired
- Optional ELEMENT flag
- Optional list of child elements, delimited by braces

Example 15.6. Add to examples:

```
create xml view "cats_e" as
  select "category"."CategoryID", "CategoryName",
    "ProductName", "ProductID"
    from "Demo".."Categories" "category", "Demo".."Products" as "product"
    where "product"."CategoryID" = "category"."CategoryID" element;

Add to text: after 'free text and xml'
```

xml_view_publish

```
DB.DBA.xml_view_publish (in view_name varchar, in dav_path varchar,
        in dav_owner varchar, in is_persistent integer, in refresh_interval integer)
```

This presents an XML view as a DAV resource. The view name is the name in the create xml view statement, note that this is case sensitive and is never converted since it is a string, not an identifier. The path must be absolute and is interpreted as relative from the DAV root collection. The DAV user is the owner of the resource. If is_persistent is non-zero the resource will be materialized from the view's description. The refresh interval is only applicable if the resource is materialized. If so, this is an interval in minutes. A value of 0 means no automatic refresh.

The reverse operation of xml_view_publish is deleting the DAV resource. xml_view_publish may be called several times to alter the owner or refresh interval.

15.3.4. External Entity References in Stored XML

When an XML document is stored as either text, long xml, xmltype or in the persistent XML format it can contain references to external parsed entities with the <!entity ...> declaration and the &xx; syntax. These are stored as references and not expanded at storage time if the entity is external.

Such references are transparently followed by XPATH and XSLT. A run time error occurs if the referenced resource cannot be accessed when needed. The reference is only followed if the actual subtree is selected by XPATH or XSLT. The resource is retrieved at most once for each XPATH or XSLT operation referencing it, regardless of the number of times the link is traversed. This is transparent, so that the document node of the referenced entity appears as if it were in the place of the reference.

External entity references have an associated URI, which is either absolute with protocol identifier and full path or relative. Relative references must be resolved with respect to the base URI of the referencing document. If the document is stored as a column value in a table it does not have a natural base URI, hence the application must supply one if relative references are to be supported. This is done by specifying an extra column of the same table to contain a path, in the form of collections delimited by slashes, just as the path of a DAV resource or a Unix file system path.

This base URI is associated with an XML column with the IDENTIFIED BY declaration:

```
create table XML_TEXT (
        XT_ID integer,
        XT_FILE varchar,
        XT_TEXT long varchar identified by xt_file,
                primary key (XT_ID)
        );

create index XT_FILE on XML_TEXT (XT_FILE);
```

Thus, each time the value of xt_text is retrieved for XML processing by XPATH_CONTAINS or XCONTAINS the base URI is taken from xt_file.

The complete URI for the xt_text of a column of the sample table will be:

```
virt://<qualified table name>.<uri column>.<text column>:<uri column value>
```

An example would be:

```
"virt://DB.DBA.XML_TEXT.XT_FILE.XT_TEXT:sqlreference.xml"
```

The .. and . in relative paths are treated as with file names when combining relative references to base URI's. A relative reference without a path just replaces the last part of the path in the base URI.

See
xml_uri_get and xml_uri_merge for more details.

15.3.5. Using XPATH in SQL Queries and Procedures

An XPATH expression can appear as a SQL query expression, that is, as a derived table or subquery predicate or scalar subquery. This means that the XPATH expression is expanded compile time to the corresponding SQL. The mapping of the XPATH hierarchy to tables and joins is given by the __view XPATH option, which is mandatory.

The XPATH keyword introduces an embedded XPATH expression. The XPATH text is presented as a string literal. Note that the tokenization rules are different for XPATH and SQL, so having XPATH as a string makes it clear which rules apply to parsing which part of the composite query.

Example 15.7. Example

```
select * from (XPATH '[__* __view "cat"]
        //product') P order by "P."ProductName"";
```

will evaluate the //product query in the context of the cat XML view and produce a result set consisting of all the attributes of the product entity as defined in the view.

Note:
The __key and __* XPATH options are central here in defining the result columns of the XPATH. The default result column of an XPATH expression is the serialization of the selected entity or scalar, which is most of the time impractical in a SQL context.

Parameters in XPATH

The '$' sign introduces a parameter in XPATH. The identifier following the dollar sign should reference a SQL column or variable defined in the surrounding context. The name of the parameter can contain a dot for referencing a column with a correlation name.

For instance, to make a VSP page that outputs the category tree which contains a specific product, one may write:

```
<HTML>
<?vsp
      declare N varchar;
      N := {?'name'};
      for (XPATH '[__http __view ''cat'']
            /category[product/@ProductName = $N]' do ; ?>
</HTML>
```

This will iterate over the categories containing a product with ProductName equal to the URL parameter 'name'. Note the __http option that causes the text of the selected entities to go directly to the HTTP client. Note the double '' escape for the XML view name inside the SQL string literal forming the name.

Also note that the N parameter is in upper case to work in all case modes. In some modes SQL identifiers will be converted automatically to upper case but this conversion does not apply inside XPATH.

```
select * from "Demo".."Categories" C
        where exists (XPATH '[__view "ord"]
        //products[@CategoryID = $C.CategoryID]');
```

This example selects the categories of products that have been mentioned in the ord XML view.

Syntax Notes

The main difference of SQL and XPATH is that the '-' is not a breaking character in XPATH and that XPATH is case sensitive without any implicit identifier case conversion.

15.3.6. XQUERY and XML view

Similarly to XPATH, XQUERY may also be used as a query language for XML views. Virtuoso offers a special case of FLWR expression for this purpose. It is possible to use the `xmlview()` function in FOR clause expressions for querying XML views. This function is similar to document () in the sense that it sets the source of the path to be the logical root of the referenced XML view. The XML view must be a constant known at compile time. A SQL query against the appropriate tables of the XML view is internally constructed and evaluated at run time, producing XML fragments from the selected rows. At no point will non-selected parts of the evaluation of the XML view be physically created. The path expression following from `xmlview()` may contain filters involving XQuery variables bound in the scope of the path expression, thus allowing joining SQL data to XQuery variable values.

The XQUERY string

```
for $cat in xmlview("cat")/category return {$cat}
```

in the query

```
select xquery_eval(' {for $cat in xmlview("cat")/category return <q>{$cat}</q>}',
                     xtree_doc('<dummy_tag/>'));
```

is equivalent to the XPATH query string

```
XPATH [__view "cat"]/category
```

described above.

The expression xmlview("viewname")/path is not a valid top level SQL statement, but may be used by xquery_eval() function. The path statement is translated into SQL query in the context of the "viewname" (i.e. the necessary table names are taken from "viewname" XML view), so that only the desired relational data will be queried. Functionality of this kind of SQL queries is similar to functionality of the SQL fetch statement, i.e. such a query provides iteration over the result set of a cursor. The query is executed once for each row in the query expression's result set. Thus using the CREATE XML VIEW statement and a XQUERY FOR clause expression with `xmlview()` function allows you to query the database and to return the results in the form of an XML document and to avoid redundant data access. This kind of queries also allows computing joins between two or more documents and restructuring data.

Note

The <dummy_tag/> tag is not used and it is necessary only as an arbitrary argument for xtree_doc() functions.

Example 15.8. Example 1

```
create xml view "product" as
{
  "Demo"."demo"."Products" p as "product"
      ("ProductID", "ProductName" as "product_name","UnitPrice" as "price",
      "SupplierID","CategoryID")
    {
      "Demo"."demo"."Suppliers" s as "supplier" ("SupplierID","CompanyName")
        on (s."SupplierID" = p."SupplierID")
       ,
      "Demo"."demo"."Categories" c as "category" ("Description")
        on (c."CategoryID" = p."CategoryID")

    }
}
```

This declares a two level hierarchy with a product node for each product and a supplier child node and a category child node of the product.

The following query will return the XML document in which each category node will contain all suppliers supplying products of the given category.

```
select xquery_eval('
  <document>
    {
      for $cat in xmlview("cat")/category
      return (
        <category description={$cat/@description}>
          {
            distinct (
              for $prod in xmlview("product")/product
              where $cat/@CategoryID=$prod/category/@CategoryID
              return $prod/supplier )
          }
        </category> )
    }
  </document>
  ',
  xtree_doc('<dummy_tag/>')
  );
```

returns the XML document in which each category node contains all suppliers supplying products of the given category.

Example 15.9. Example 2

Let a document named suppliers.xml contains supplier elements; each supplier element in turn contains supplier_id and supplier_name subelements. The following query

```
select xquery_eval('
  <supplier_product>
    {
      for $supp in document("suppliers.xml")/supplier
      return (
        <supplier>{$supp/supplier_name }
          <product_name>
            {
              for $prod in xmlview("product")/product
              where string($supp/supplier_id)=$prod/supplier/@SupplierID
              return string($prod/@product_name)
            }
          </product_name>
        </supplier>)
    }
  </supplier_product>',
  xtree_doc('<dummy_tag/>')
  );
```

returns the XML document that contains supplier elements; each supplier element in turn contains supplier_name and product_name elements.

The previous query and the following one show that it is possible to use variables in a XPATH expression following `xmlview()` functions.

Example 15.10. Example 3

The query

```
select xquery_eval('
  <document>
    {
      distinct(
        let $ex:= "Ex%"
        for $prod in xmlview("product")//supplier[@CompanyName like $ex]
        return <supp_id>{$prod/@SupplierID}</supp_id>)
    }
  </document>',
```

```
  xtree_doc('<dummy_tag/>'));
```

is equivalent to

```
select xquery_eval('
  <document>
    {
      distinct(
        for $prod in xmlview("product")//supplier [@CompanyName like "Ex%"]
        return <supp_id>{$prod/@SupplierID}</supp_id>)
    }
  </document>',
  xtree_doc('<dummy_tag/>'));
```

and selects all suppliers having attribute "CompanyName" starting with "Ex".

Optimization in the queries with xmlview() function

At least two methods may be used to accelerate the execution of queries with xmlview() function. The first method assumes that a path statement following xmlview() function should contain maximum conditions to reduce the result set. For example, the query

```
select xquery_eval('<w>
  {
    for $prod in xmlview("product")/product[@ProductID="1"]
    return <q>{$prod}</q>
  }</w>',
  xtree_doc('<dummy_tag/>'));
```

will be executed faster than

```
select xquery_eval('<w>
  {
    for $prod in xmlview("product")/product where $prod[@ProductID="1"]
    return <q>{$prod}</q>
  }</w>',
  xtree_doc('<dummy_tag/>'));
```

due to the SQL query produced from the path expression 'product[@ProductID="1"]' reduces the result set in comparison with the SQL query produced from the path expression 'product' in the second query.

If we execute a join of two (or more) XML views (or XML document and XML view), i.e. the query consists of the nested loops, the second method proposes to carry out a piece of query of the nested loop which is independent of the outer loop outside the outer loop and uses LET clause for it. For example, the query

```
select xquery_eval('<document>
  {
    let $prod_set:=(for $prod in xmlview("product")/product return $prod)
    for $cat in xmlview("cat")/category
    return (<category description={$cat/@description}$gt;
      {distinct(for $prod in $prod_set
                where $cat/@CategoryID=$prod/category/@CategoryID
                return $prod/supplier)}</category>)}</document>',
   xtree_doc('<dummy_tag/>'));
```

is equivalent to the query in the example 1, but it is about 5 times faster than original one. This method is especially useful for full joins. In this case we do not have a full join and this query may be optimized without the use of temporary result sets if the 'where' clause is replaced with proper filter:

```
select xquery_eval('<document>
  {
    for $cat in xmlview("cat")/category
    let $catID := $cat/@CategoryID
    return (<category description={$cat/@description}$gt;
      {distinct(
        for $supp in xmlview("product")/product[category/@CategoryID=$catID]/supplier
        return $supp)
```

```
        }</category>)
    }
    </document<',
    xtree_doc('<dummy_tag/>'));
```

This variant requires no memory for storing $prod_set and it never fetches redundant fields from "Demo"."demo"."Products" table but it heavily needs index for "Demo"."demo"."Products" on "CategoryID" field. If such index is built the last variant is about 10 times faster than the query in example 1. Similarly, the query in example 2 may be optimized as follows:

```
select xquery_eval('
  <supplier_product>
   {
     for $supp in document("suppliers.xml")/supplier
     let $supp_id:=string($supp/@supplier_id)
     return (
      <supplier>{$supp/supplier_name}
        <product_name>
          {
            for $prod in xmlview("product")/product[supplier/@SupplierID=$supp_id]
            return string($prod/@product_name)
          }
        </product_name>
      </supplier>)
   }
  </supplier_product>',
  xtree_doc('<dummy_tag/>')
  );
```

and it speeds up the operation by more than 15 times.

Restrictions in XPATH expressions following the xmlview() function

Virtuoso does not support certain kinds of XPATH expressions applied to the xmlview() function.

1. A path expression must not contain any functions, because it is impossible to translate most of the functions to SQL queries.

2. A path expression must not contain numeric XQUERY variables in the arithmetic expressions. Let a document named products.xml contains product elements; each product element has numeric attribute ProductPrice. A run time error occurs if the following query would be used

```
select xquery_eval('
  <document>
   {
     for $prod_doc in document("products.xml")/products/product/@ProductPrice
       for $prod_view in xmlview("product")/product[@price>$prod_doc+1]
     return <q>{$prod_doc, $prod_view/@product_name}</q>
   }
   </document>',
   xtree_doc('<dummy_tag/>'));
```

because the type of $prod_doc is considered as string. As it is mentioned in the previous restriction the using a function in a path expression (e.g. xmlview("product")/product[@price>number($prod_doc)+1]) is not allowed. The correct query is as follows:

```
select xquery_eval('
  <document>
    {
      for $prod_doc in document("products.xml")/products/product/@ProductPrice
        let $prod_doc2:=number($prod_doc)
        for $prod_view in xmlview("product")/product[@price>$prod_doc2+1]
      return <q>{$prod_doc, $prod_view/@product_name}</q>
    }
  </document>',
  xtree_doc('<dummy_tag/>'));
```

3. A path expression must not contain XQUERY variables with the following paths. The following query will not be executed

```
select xquery_eval('
  <document>
```

```
    {
      for $cat in xmlview("cat")/category,
          $prod in xmlview("product")/product[@CategoryID=$cat/@CategoryID]
      return <q>{$prod/supplier}</q>
    }
  </document>',
  xtree_doc('<dummy_tag/>'));
```

The correct query may be given as

```
select xquery_eval('
  <document>
    {
      for $cat in xmlview("cat")/category
      let $cat_id:=$cat/@CategoryID
      for $prod in xmlview("product")/product[@CategoryID=$cat_id]
      return <q>{$prod/supplier}</q>
    }
  </document>',
  xtree_doc('<dummy_tag/>'));
```

4. Virtuoso does not support a selection of n-th element in a path expression. The following query will not be executed

```
select xquery_eval('
  <document>
    {
      for $cat in xmlview("cat")//product[1] return <q>{$cat}</q>
    }
  </document>',
  xtree_doc('<dummy_tag/>'));
```

5. Virtuoso does not support a dereference (=>) in a path expression.

6. It is not recommended to use the long varchar, long varbinary and long nvarchar data types with the logical and boolean operations in a filter of the path expression. For example, the execution of the following query

```
select xquery_eval('
  <document>
    {
      for $prod in
        xmlview("product")/product[@SupplierID<5]/category[@Description like "Sw%"]
      return <q>{$prod}</q>
    }
  </document>',
  xtree_doc('<dummy_tag/>'));
```

may return an error, because the field "Description" has LONG VARCHAR type in the table "demo"."Categories".

15.3.7. Mapping Schemas as XML Views

Virtuoso supports creating XML views by using annotated XSD schemas referred to as mapping schemas. A file containing a mapping schema may be loaded by calling the `xml_load_mapping_schema_decl()` function. A name (without extension .xsd) of the file containing a mapping schema is considered to be the name of the xml view, defined by the given mapping schema.

A loaded mapping schema may be queried in the same way as one would query XML views defined using the CREATE XML VIEW statement with XPATH:

```
XPATH [__view "xml_view_name"]/xpath_query
```

Example 15.11. Loading and Querying a Mapping Schema

The XML view "Catmp" from the file "Catmp.xsd" may be loaded using the following statement:

```
 select  xml_load_mapping_schema_decl (
    'http://localhost.localdomain/xmlrepository/',
    'Catmp.xsd',
```

```
        'UTF-8',
        'x-any' ) ) );
```

where the contents of "Catmp.xsd" is

```
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
            xmlns:sql="urn:schemas-microsoft-com:mapping-schema">
<xsd:annotation>
  <xsd:appinfo>
    <sql:relationship name="CategoryProduct"
          parent="Demo.demo.Categories"
          parent-key="CategoryID"
          child="Demo.demo.Products"
          child-key="CategoryID" />
  </xsd:appinfo>
</xsd:annotation>

  <xsd:element name="category" sql:relation="Demo.demo.Categories" type="CategoryType" />
   <xsd:complexType name="CategoryType" >
     <xsd:sequence>
        <xsd:element name="product"
                    sql:relation="Demo.demo.Products"
                    sql:relationship="CategoryProduct" >
           <xsd:complexType>
              <xsd:attribute name="ProductName" type="xsd:string" />
           </xsd:complexType>
        </xsd:element>
     </xsd:sequence>
        <xsd:attribute name="CategoryID"  type="xsd:integer" />
        <xsd:attribute name="description"  sql:field="Description"  type="xsd:string" />
    </xsd:complexType>
</xsd:schema>
```

The XML view "Catmp" loaded from the file "Catmp.xsd" is similar to XML view "cat" defined by CREATE XML VIEW in the section Explicit Xml Views .

The query

```
XPATH [__view 'Catmp'] /category[@* = 1];
```

will now return the following result:

```
<category CategoryID="1" description="Soft drinks, coffees, teas, beers, and ales" >
  <product ProductName="Chai" ></product>
  <product ProductName="Chang" ></product>
  <product ProductName="Guarana Fantastica" ></product>
  <product ProductName="Sasquatch Ale" ></product>
  <product ProductName="Steeleye Stout" ></product>
  <product ProductName="Cote de Blaye" ></product>
  <product ProductName="Chartreuse verte" ></product>
  <product ProductName="Ipoh Coffee" ></product>
  <product ProductName="Laughing Lumberjack Lager" ></product>
  <product ProductName="Outback Lager" ></product>
  <product ProductName="Rhonbrau Klosterbier" ></product>
  <product ProductName="Lakkalikoori" ></product>
</category>
```

Mapping schemas provide more flexibility than XML views defined by the `CREATE XML VIEW` statement. In the following mapping schema a constant element, "CustomerOrders", an element that does not map to any database table or column but may appear in the resulting XML as a container element of other subelements, is specified by the `sql:is-constant` annotation.

```
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
            xmlns:sql="urn:schemas-microsoft-com:mapping-schema">
<xsd:annotation>
  <xsd:appinfo>
    <sql:relationship name="CustOrders"
```

```
        parent="Demo.demo.Customers"
        parent-key="CustomerID"
        child="Demo.demo.Orders"
        child-key="CustomerID" />
  </xsd:appinfo>
</xsd:annotation>

  <xsd:element name="Customer" sql:relation="Demo.demo.Customers" >
    <xsd:complexType>
      <xsd:sequence>
        <xsd:element name="CustomerOrders" sql:is-constant="1" >
          <xsd:complexType>
            <xsd:sequence>
              <xsd:element name="Order" sql:relation="Demo.demo.Orders"
                           sql:relationship="CustOrders"
                           maxOccurs="unbounded" >
                <xsd:complexType>
                   <xsd:attribute name="OrderID" type="xsd:integer" />
                   <xsd:attribute name="OrderDate" type="xsd:date" />
                   <xsd:attribute name="CustomerID" type="xsd:string" />
                </xsd:complexType>
              </xsd:element>
            </xsd:sequence>
          </xsd:complexType>
        </xsd:element>
      </xsd:sequence>
          <xsd:attribute name="CustomerID" type="xsd:string" />
    </xsd:complexType>
  </xsd:element>
</xsd:schema>
```

After loading the "Cust_constant.xsd" file containing the given mapping schema, the xpath query:

```
XPATH [__view 'Cust_constant'] /category[@* = 1];
```

will return the following result:

```
<Customer CustomerID="ALFKI" >
  <CustomerOrders >
    <Order CustomerID="ALFKI" OrderDate="1995-09-25 00:00:00.000000" OrderID="10643" ></Order>
    <Order CustomerID="ALFKI" OrderDate="1995-11-03 00:00:00.000000" OrderID="10692" ></Order>
    <Order CustomerID="ALFKI" OrderDate="1995-11-13 00:00:00.000000" OrderID="10702" ></Order>
    <Order CustomerID="ALFKI" OrderDate="1996-02-15 00:00:00.000000" OrderID="10835" ></Order>
    <Order CustomerID="ALFKI" OrderDate="1996-04-15 00:00:00.000000" OrderID="10952" ></Order>

    . . .
```

Virtuoso does not support all mapping schema annotations at this time. The following are currently unsupported:

`sql:encode`
`sql:use-cdata`
`sql:overflow-field`
`sql:inverse`
`sql:hide`
`sql:guid`
`sql:max-depth`

Also, there are some restrictions to the structure of mapping schemas:

Attributes can not contain sql:relationship annotation.
Subelement having no sql:is-constant annotation and not mapped to any table can not contain subelements and attributes.
Recursive relationships is not supported.

 **Note:**

Note:

The XML views, defined by mapping schemas may not be queried using XQUERY. They can however be referenced with the xmlview XPATH functions in path expressions inside an XQuery query.

See Also:

SQLXML 3.0 documentation: Creating XML Views by Using Annotated XSD Schemas.

15.3.8. Differences Between SQLX, FOR XML and XML Views

A SQLX or FOR XML query has no effect on the database schema. It is a transient event and does not generate procedures or other schema elements.

These define an ad hoc mapping of a result set to XML. There is no possibility of using XPATH to specify a search without first constructing the whole tree. An XML view on the other hand provides a mapping context in which one can make XQUERY or XPATH queries that are mapped into SQL and the XML is only generated after applying the conditions.

XML views will usually be more efficient in complex cases and the notation there may be simpler than the EXPLICIT notation in FOR XML. For simple cases SQLX or FOR XML is the more convenient of the two. SQLX or FOR XML does not restrict the SQL being used and will allow free use of subqueries, expressions, derived tables, qualified joins etc.

15.4. Querying Stored XML Data

15.4.1. XPATH_CONTAINS SQL Predicate

XPath expressions can be used in SQL statements to decompose and match XML data stored in columns. The *xpath_contains* SQL predicate can be used either to test for an XML value matching a path expression or to extract one or more entities from the XML value. These values can then be used later in the query as contexts for other XPath expressions.

```
xpath_contains (xml_column, xp_expression[, query_variable]);
```

The first argument, *xml_column* is the name of the column on which to perform the XPath search. The second argument, *xp_expression* , takes an XPath expression.

The third argument is an optional query variable that gets bound to each result entity value of the xpath expression. If this variable is omitted the xpath_contains predicate will qualify the query by returning true for matches. In this case the result will only return one row per match. If the variable is present, the result set could contain multiple rows per result set row of the base table, one row for each match.

Consider the example:

```
select xt_file, t from xml_text
  where xpath_contains (xt_text, '//chapter/title[position () = 1]', t);
```

This SQL statement will select the first title child of any chapter entities in the XML documents in the xt_text column of the table *xml_text* . There can be several matching entities per row of xml_text. The result set will contain a row for each matching entity.

In XPath terms the path expression of *xpath_contains* is evaluated with the context node set to the root node of the XML tree represented by the value of the column that is the first argument of xpath_contains. This node is the only element of the context node set.

Note:

The 't' variable in the above example gets bound to XML entities, not to their string values or other representations. One can thus use these values as context nodes for other expressions.

The XPATH expression can have a list of options in the beginning. The list of options is surrounded by square brackets. Options in the list are delimited by spaces. The most popular option is *__quiet* that allows to process a set of rows if not all stored documents are valid XMLs; if an error is signalled by the XML parser when it prepares a content document for the XPATH in question and the XPATH contains *__quiet* then the error is suppressed and the row is silently ignored as if XPATH found nothing. One can configure the DTD validator of the parser by placing its configuration parameters in the list of XPATH options.

The following example is almost identical to the previous one but it works even if not all values of *xt_text* are valid XMLs, and the resulting values of the 't' variable are standalone entities even if source documents in xt_text contain external generic entities.

```
select xt_file, t from xml_text
  where xpath_contains (xt_text, '[__quiet BuildStandalone=ENABLE]//chapter/title[position () = 1]', t);
```

15.4.2. Using xpath_eval()

The `xpath_eval()` function is used to filter out parts of an XML fragment that match a given XPATH expression. It can be used to retrieve multiple-node answers to queries, as it is often the case that more than one node-set matches. Consider the following statements that create a table with XML stored inside.

```
CREATE TABLE t_articles (
        article_id int NOT NULL,
        article_title varchar(255) NOT NULL,
        article_xml long varchar
        );

insert into t_articles (article_id, article_title) values (1, 'a');
insert into t_articles (article_id, article_title) values (2, 'b');

UPDATE t_articles SET article_xml = '
<beatles id = "b1">
<beatle instrument = "guitar" alive = "no">john lennon</beatle>
<beatle instrument = "guitar" alive = "no">george harrison</beatle>
</beatles>'
WHERE article_id = 1;

UPDATE t_articles SET article_xml = '
<beatles id = "b2">
<beatle instrument = "bass" alive = "yes">paul mccartney</beatle>
<beatle instrument = "drums" alive = "yes">ringo starr</beatle>
</beatles>'
WHERE article_id = 2;
```

Now we make a query that will return a vector of results, each vector element corresponding to a node-set of the result.

```
SELECT xpath_eval('//beatle/@instrument', xml_tree_doc (article_xml), 0)
        AS beatle_instrument FROM t_articles WHERE article_id = 2;
```

The repeating nodes are returned as part of a vector, the third argument to `xpath_eval()` is set to 0, which means that it is to return all nodes.

Otherwise, we can select the first node-set by supplying 1 as the third parameter to `xpath_eval()` :

```
SELECT xpath_eval('//beatle/@instrument', xml_tree_doc (article_xml), 1)
        AS beatle_instrument FROM t_articles WHERE article_id = 2;
```

`xmlupdate()`

15.4.3. External Entity References in Stored XML

When an XML document is stored as either text or in persistent XML format it can contain references to external parsed entities with the <!entity ...> declaration and the &xx; syntax. These are stored as references and not expanded at storage time if the entity is external. Such references are transparently followed by XPath and XSLT. A run-time error occurs if the referenced resource cannot be accessed when needed. The reference is only followed if the actual subtree is selected by XPath or XSLT. The resource is retrieved at most once for each XPath or XSLT operation referencing it, regardless of the number of times the link is traversed. This is transparent, so that the document node of the referenced entity appears as if it were in the place of the reference.

External entity references have an associated URI, which is either absolute, with protocol identifier and full path, or relative. Virtuoso resolves relative references with respect to the base URI of the referencing document. If the document is stored as a column value in a table it does not have a natural base URI; therefore, the application must supply one if relative references are to be supported. This is done by specifying an extra column of the same table to contain a path, in the form of collections delimited by slashes, like the path of a DAV resource or a Unix file system path. This base URI is associated with an XML column with the IDENTIFIED BY declaration:

```
create table XML_TEXT (
        XT_ID integer,
        XT_FILE varchar,
        XT_TEXT long varchar identified by xt_file,
                primary key (XT_ID)
        );

create index XT_FILE on XML_TEXT (XT_FILE);
```

Thus, each time the value of *xt_text* is retrieved for XML processing by `xpath_contains()` or `xcontains()` the base URI is taken from *xt_file* . The complete URI for the *xt_text* of a column of the sample table would be:

```
virt://<qualified table name>.<uri column>.<text column>:<uri column value>
```

An example would be:

```
"virt://DB.DBA.XML_TEXT.XT_FILE.XT_TEXT:sqlreference.xml"
```

The '..' and '.' in relative paths are treated like file names when combining relative references to base URIs. A relative reference without a path just replaces the last part of the path in the base URI.

See Also:

`xml_uri_get()` and `xml_uri_merge()` for more details.

15.4.4. XML Schema & DTD Functions

The following functions can be used to generate XML Schema or DTD information about a given SQL query:

`xml_auto_schema()`

`xml_auto_dtd()`

Example 15.12. Generating XML Schema and DTD Data

This example shows trivial use of the two functions `xml_auto_schema()` and `xml_auto_dtd()` .

```
SQL> select xml_auto_schema('select u_name from sys_users', 'root');
callret
VARCHAR
_______________________________________________________________________________

<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema">

 <xsd:annotation>
  <xsd:documentation>
   Schema for output of the following SQL statement:

   <![CDATA[select u_name from sys_users]]>

  </xsd:documentation>
 </xsd:annotation>

 <xsd:element name="root" type="root__Type"/>

 <xsd:complexType name="root__Type">
  <xsd:sequence>
   <xsd:element name="SYS_USERS" type="SYS_USERS_Type" minOccurs="0" maxOccurs="unbounded"/>
  </xsd:sequence>
 </xsd:complexType>

 <xsd:complexType name="SYS_USERS_Type">
  <xsd:attribute name="U_NAME" type="xsd:string"/>
```

```
 </xsd:complexType>

</xsd:schema>

1 Rows. -- 1843 msec.
SQL> select xml_auto_dtd('select u_name from sys_users', 'root');
callret
VARCHAR
_______________________________________________________________________________

<!-- dtd for output of the following SQL statement:
select u_name from sys_users
-->

<!ELEMENT root (#PCDATA | SYS_USERS)* >
<!ELEMENT SYS_USERS (#PCDATA)* >
<!ATTLIST SYS_USERS
        U_NAME  CDATA   #IMPLIED        >

1 Rows. -- 411 msec.
```

15.4.5. Using XML and Free Text

Virtuoso integrates classic free text retrieval and XML semi-structured query features to offer a smart, scalable XML repository. When a column is declared as indexed XML with the CREATE TEXT XML INDEX statement the text is checked for well-formedness at time of storage. The specific XML structure of the text is also considered when making the free text index entries. This XML-aware free text index is used for processing XPath queries in the *xcontains* SQL predicate. This predicate is only applicable to columns for which there is an XML free text index.

Arbitrary free text criteria can appear inside the XPath expression of *xcontains* . These are introduced by the XPath extension function `text-contains()` , which may only be used within *xcontains* as it relies on the underlying free text index.

Note

`xpath_contains()` does not require the existence of a free text index and can thus apply to any well-formed XML content.

15.4.6. XCONTAINS predicate

This predicate is used in a SQL statement, it returns "true" if a free text indexed column with XML content matches an XPATH expression. Optionally produces the matching node set as a result set.

Syntax

```
xcontains_pred:
        xcontains (column, expr [, result_var [, opt_or_value ...]])

opt_or_value:
          DESCENDING
          | START_ID ',' scalar_exp
          | END_ID ',' scalar_exp
          | SCORE_LIMIT ',' scalar_exp
          | OFFBAND column

result_var:
          IDENTIFIER
          | NULL
```

The *column* must refer to a column for which there exists a free text index.

The *expr* must be a narrow or wide string expression whose syntax matches the rules in 'XPATH Query Syntax'.

The *result_var* variable is a query variable which, if present, will be successively bound to each element of the node set selected by the XPATH expression. if the value is not a node set and is true, the variable will be once bound to this value. The scope of the variable is the containing select and its value is a scalar or an XML entity. The *result_var* can be not an identifier but a NULL keyword to explicitly indicate that no query variable is required.

The *START_ID* is the first allowed document ID to be selected by the expression in its traversal order, e.g. least or equal for ascending and greatest or equal for descending.

END_ID is the last allowed id in the traversal order. For descending order the START_ID must be >= END_ID for hits to be able to exist. For ascending order the START_ID must be <= END_ID for hits to be able to exist.

DESCENDING specifies that the search will produce the hit with the greatest ID first, as defined by integer or composite collation. This has nothing to do with a possible ORDER BY of the enclosing statement. Even if there is an ORDER BY in the enclosing statement the DESCENDING keyword of xcontains has an effect in the interpretation of the STRT_ID and END_ID xcontains options.

RANGES specifies that the query variable following the RANGES keyword will be bound to the word position ranges of the hits of the expression inside the document. The variable is in scope inside the enclosing SELECT statement.

SCORE_LIMIT specifies a minimum score that hits must have or exceed to be considered matches of the predicate.

OFFBAND specifies that the following column will be retrieved from the free text index instead of the actual table. For this to be possible the column must have been declared as offband with the CLUSTERED WITH option of the CREATE TEXT INDEX statement.

If the select statement containing the xcontains predicate does not specify an exact match of the primary key of the table having the xcontains predicate, then the contains predicate will be the 'driving' condition, meaning that rows come in ascending or descending order of the free text document ID. If there is a full equality match of the primary key of the table, this will be the driving predicate and xcontains will only be used to check if the text expression matches the single row identified by the full match of the primary key.

The xcontains predicate may not appear outside of a select statement and may only reference a column for which a free text index has been declared. The first argument must be a column for which there is such an index. The text expression may be variable and computed, although it must be constant during the evaluation of the select statement containing it.

The xcontains predicate must be a part of the top level AND of the WHERE clause of the containing select. It may not for example be a term of an OR predicate in the select but can be AND'ed with an OR expression.

Example 15.13. Selecting Title Elements Called 'Key'

```
select xt_file from xml_text2 where
 xcontains (xt_text, '//title = "Key"');
```

The query retrieves the *xt_file* for rows whose *xt_text* is an XML document containing 'Key' as the text value of a title element.

If not all values in *xt_text* are valid XMLs then '__quiet' option can be useful to disable error signalling. It is unusual to get an incorrect XML stored in a column that has free text XML index because both on insert and on update the text is parsed by an free text indexing routine, but the error is possible if e.g. a non-standalone document is stored and an important external entity was available at indexing time but disappeared later. Thus a modified example might be better for a column with non-standalone documents;

```
select xt_file from xml_text2 where
 xcontains (xt_text, '[__quiet] //title = "Key"');
```

Selecting Title Element that Contains a Specified Text

```
select n from xml_text2 where
 xcontains(xt_text,
 '//title[. = "AS Declaration - Column Aliasing"]',0,n);
```

The query retrieves each title element from each row of *xml_text2* where the *xt_text* contains title elements with the text value "AS Declaration - Column Aliasing."

Note

The equality test is case- and whitespace-sensitive, as normal in XPath. The free text index is used for the search but the final test is done according to XPath rules.

See Also:
The CONTAINS Predicate.

15.4.7. text-contains XPath Predicate

```
text-contains (node-set, text-expression)
```

This XPath predicate is true if any of the nodes in *node-set* have text values matching the *text-expression*. The *text-expression* should be a constant string whose syntax corresponds to the top production of the free text syntax for patterns in `contains()`. The string also may not consist exclusively of spaces or noise words.

See Also:
"Noise Words" in the Free Text Search chapter .

Example 15.14. Selecting All Titles About Aliasing

```
select n from xml_text2 where
  xcontains (xt_text,
  '//title[text-contains (., "Aliasing")]', 0, n);
```

This selects all title elements that contain the word "Aliasing" using free text match rules: case insensitive and whole word.

Example 15.15. Select All Trees with Elements Containing "sql reference"

```
select n from xml_text2 where
  xcontains (xt_text,
  '//*[text-contains (., '"sql reference"')]',
  0, n);
```

This selects all elements whose text value contains the phrase "sql reference". Free text matching rules apply. This produces all nodes in document order for all documents which contains the phrase, starting with the document node and following downward including all paths to the innermost element(s) whose text contains the phrase.

15.4.8. XML Free Text Indexing Rules

XML documents are inserted into the free text index as follows:

The process works on the parsed XML tree; therefore character and local entity references are expanded.

Whole words of text content, bounded by delimiters used for free text, are each assigned an ordinal number. Noise words defined in the noise.txt file used by free text indexing are not counted.

Attribute names and values are not indexed.

Element start and end tags are indexed using the expanded names - that is, prefixed with the namespace URI + ':'.

An element start tag's ordinal number is one less than the ordinal number of the first whole word in the text value.

A close tag's ordinal number is one greater than that of the last word in the text value.

From these rules follows that:

```
<html>
  <body>
   <title>Title of Document</title>
   <p>Some <b>bold</b> text </p>
  </body>
</html>
```

will be indexed as follows:

```
<html>          0
<body>          0
<title>         0
```

```
Title           1
of              - no number, noise word
Document                2
</title>                3
   <p>          3
Some            4
 <b>            4
bold            5
</b>            6
 text           6
</p>            6
  </body>               6
</html>         6
```

As a result, the phrase "some bold text" is the string value of the <p> tag and will match the free text expression "some bold text" even though there is mark-up in it. Conversely, the phrase "Document some bold" does not match. Words will not considered adjacent if there is a mix of opening and closing tags. They will only be considered adjacent if there are solely one or more either opening or closing tags between them. This can be circumvented by using the *NEAR* connective instead of the phrase construct.

A free text condition will only be true of an element if all the words needed to satisfy the condition are part of the element's string value. This string value includes text children of descendants.

15.4.9. XML Processing & Free Text Encoding Issues

XML document may be written in a variety of encodings, and it may cause errors if an incorrect encoding is used for reading a document. Most common errors can easily be eliminated by writing proper XML prologs in documents, but this is not always possible, e.g. if documents are composed by third-party applications. Virtuoso provides various tools to support different types of encodings and to specify encodings to use if a given document has no XML prolog.

Encodings: The Difference Between Encodings & Character Sets

Not all documents may be converted to Unicode by using simple character sets. Some of them are stored in so-called "multibyte" encodings. It means that every letter (or ideograph) is represented as a sequence of one or more bytes, not by exactly one byte. The conversion from such representation to Unicode and back is usually significantly slower than simple transformation via character sets, so these representations are supported by data import operations only, but not by internal RDBMS routines.

The Virtuoso Server "knows" some number of built-in encodings, such as UTF-8, UTF-16BE and UTF-16LE. It can load additional encoding descriptions from a "UCM" file, and can automatically create a new encoding from a known charset with the same name. See the UCM Encodings section for more details.

An encoding may be used in the following places:

The XML/HTML parser to convert source text to Unicode.

The free-text indexing engine to convert plain-text or XML documents to Unicode during the indexing.

It may be used by the compiler of free-text search expressions to convert string constants of the expression to Unicode.

It may be used to convert string constants of XPath/XQuery expressions.

You can only use character sets, not encodings as an ODBC connection character set, as a character set attribute of a column of a database table, as an output encoding of the built-in XSLT processor (it is for future versions). UTF-8 is an exception, it is supported in many places where other encodings are not.

Security Note:

Two strings converted to Unicode may be identical, but this does not guarantee that their source strings were equal byte-by-byte due to the nature of some encodings. For this reason you should avoid processing authorization data that are neither in Unicode nor in one of the standard character sets (single-byte encodings). Multibyte encodings and user-defined character sets may be unsafe for such purposes.

UCM Encodings

The description of a multibyte encodings is much longer than the description of a character set. It is inconvenient to keep such amounts of data inside the executable. Virtuoso can load descriptions of required encodings from external files in UCM format. Every UCM file describes one encoding.

Virtuoso loads UCM files at system initialization. The list of UCM files is kept in the Virtuoso INI file under a section called [Ucms]. This section should contain a UcmPath parameter and one or more parameters with names Ucm1, Ucm2, Ucm3 and so on (up to Ucm99).

The UcmPath parameter specifies the directory where UCM files are located, and every UcmNN parameter specifies the name of a UCM file to load and a list of names that the encoding can be identified by the <?xml ... encoding="..." ?> XML preamble. A vertical bar character is used to delimit names in the list.

Example 15.16. Sample [Ucms] Section

```
[Ucms]
UcmPath = /usr/local/javalib/ucm
Ucm1 = java-Cp933-1.3-P.ucm,Cp933
Ucm2 = java-Cp949-1.3-P.ucm,Cp949|Korean
```

This section describes two UCM files located in /usr/local/javalib/ucm directory: data from java-Cp933-1.3-P.ucm will be used for documents in the 'Cp933' encoding; data from java-Cp949-1.3-P.ucm will be used for documents in the 'Cp949' encoding and for documents in the 'Korean' encoding (because these two names refers to the same encoding).

Note:

The encoding name specified inside the UCM file itself is not used.

The Virtuoso server will log the results of processing each UCM file specified in the Virtuoso INI file. If a UCM file specified is not found or contains syntax errors, the error is logged, otherwise only the type and name(s) of the encoding are logged.

Note:

If the virtuoso.ini contains a misspelled name of a parameter or section, the parameter (or a whole section) is ignored without being reported as an error. It is always wise to verify that the log contains a record about the encoding(s) you load.

See Also:

UCM files can be found freely from various sites concerning the "International Components for Unicode" project, such as: IBM ICU Homepage or the IBM UCM files directory .

The C Interface chapter contains further information regarding user customizable support for new encodings and languages. For almost all tasks, it is enough to define a new charset or to load an additional UCM file, but some special tasks may require writing additional C code.

The *Encoding* Attribute

If an XML document contains the *encoding* parameter in its

```
<?xml ... ?>
```

prolog declaration, it will be properly decoded and converted into UTF-8, so the application code is free from encoding problems. If the value of this attribute is the name of a pre-set or user-defined character set, that character set will be used. Virtuoso will recognize names such as *UTF-8* and *UTF8* as multi-character or special encodings. Virtuoso recognizes both official names and aliases.

If an encoding is not specified in an XML prolog, or if the document contains no prolog, the default encoding will be used to read the document. If a built-in SQL function invokes the XML parser, it will have an optional argument *parser_mode* to specify whether source text should be parsed as strict XML or as HTML. If the source text is 8-bit, then UTF-8 will be used as the default encoding for "XML mode", and ISO-8859-1 (Latin-1) will be the default for "HTML mode". If the source text is of some wide-character type, Unicode is the default. To make another encoding the default, you may specify its official or alias name as the *content_encoding* argument of a built-in function you call.

Encoding in XPath Expressions

Sometimes applications should perform XPath queries using the encoding specified by a client. For example, a search engine may ask a user to specify a pattern to search and use the browser's current encoding as a hint to parse the pattern properly. In such cases you may wish to use the *__enc* XPath option to specify the encoding used for the rest of XPath string:

Example 15.17. Specifying Search Encodings in XPath

Create a sample table and store an XML with non-Latin-1 characters

```
create table ENC_XML_SAMPLE (
  ID integer,
  XPER long varchar,
  primary key (ID)
);

insert into ENC_XML_SAMPLE (ID, XPER)

values (
  1,
  xml_persistent ('<?xml version="1.0" encoding="WINDOWS-1251" ?>
    <book><cit>Îí äîáàâëë
      êàðòîøêè,
    ïîñîëèë è
    ïîñòàâèë
    àêâàðèóì íà
    îãîíü
    (Ì.Æâàíåöêèé
    )</cit></book>'
  )
);
...
```

Find the IDs of all XML documents whose texts contain a specified phrase. Note that there are pairs of single quotes (not double quotes) around *KOI8-R* . The encoding name should be in single quotes, but because it is inside a string constant the quotes must be duplicated.

```
select ID from ENC_XML_SAMPLE where
  xcontains (XPER, '[__enc ''KOI8-R''] //cit[text-contains(.,
  "''ÐÏÓÔÁ×ÉÌ
    ÁË×ÁÒÉÕÍ
    ÎÁ ÏÇÏÎØ''")]');
```

Encoding in Free Text Search Indexes & Patterns

Like XML applications, free text searching may have encoding problems, and Virtuoso offers a similar solution for them.

Both the CREATE TEXT INDEX statement and vt_create_text_index() Virtuoso/PL procedure have an optional argument to specify the encoding of the indexed data. The specified encoding will be applied to all source text documents (if the TEXT INDEX was created), or to all XML documents that have no encoding attribute of the sort <?xml ... encoding="..." ?> (if the TEXT XML INDEX was created).

The option __*enc* may be specified at the beginning of free text search pattern, even if the pattern is inside an XPath statement:

Example 15.18. Specifying an Encoding for Free Text Searching

Create a sample table and store a sample of text with non-Latin-1 characters (assuming that client encoding is Windows-1251)

```
create table ENC_TEXT_SAMPLE (
  ID integer,
  TEXT long nvarchar,
  primary key (ID)
);

insert into ENC_TEXT_SAMPLE (ID, XPER)
```

```
values (
  1,
  '<?xml version="1.0" encoding="WINDOWS-1251" ?>
Îí äîáàâëë
    êàðòîøêè,
    ïîñìîòðè è
    ïîñòàâëë
    àêâàðèóì
    íà îãîíü
    (È.Æâàíåöêèé')
);
...
```

Find the IDs of all text documents whose texts contain a specified phrase.

```
select ID from ENC_SAMPLE where
  contains (TEXT, '[__enc ''KOI8-R'']
    "ÐÏÓÔÁ×ÉÌ
    ÁË×ÁÒÉÕÍ
    ÎÁ ÏÇÏÎØ"'
  );
```

Encoding may be applied locally to an argument of the text-search predicate. It may be used if the document contains citations in different encodings or if the XML document contains non-ASCII characters in names of tags or attributes, or if the encoding affects character codes of ASCII symbols such as '/' or '['.

```
select ID from ENC_XML_SAMPLE where
  xcontains (XPER, '//cit[text-contains(., "[__enc ''KOI8-R'']
    ''ÐÏÓÔÁ×ÉÌ
    ÁË×ÁÒÉÕÍ ÎÁ
    ÏÇÏÎØ''")]'
  );
```

Note:
You may have free-text a expression written as a literal constant: e.g. if the argument of text-contains XPath function is a literal constant. Be careful to not declare the __enc twice, once in the beginning of the whole XPath expression and then again in the beginning of the free-text expression constant, because words of the text expression will thus be converted twice.

15.5. Using UpdateGrams to Modify Data

Updategrams allow database updates to be defined as XML. This is ultimately achieved by mapping the XML nodes against corresponding database columns. Updategrams can be used to replace existing data access components in a middle tier. A typical application will include a middle tier consisting of business logic and data access code. The data access code will interact with the database using disconnected recordsets and command objects calling stored procedures. Most of the data access section of the middle tier can be replaced with updategrams.

Most data access tiers (both middle tier code and stored procedures) will deal individually with specific database tables or groups of related tables. This can inhibit performance and often several round trips to the database are required to complete a transaction. Updategrams solve this problem by including all the data in an XML document that is then mapped to database tables and columns. The entire database update can then be accomplished at once. This update can include inserting, updating and deleting data.

The `xmlsql_update()` function supports XML-based insert, update, and delete operations performed on an existing table in the database. `xmlsql_update()`

15.5.1. Updategrams Basics

The general format of an updategram is:

```
<sql:sync xmlns:sql="xml-sql">
 <sql:before>
    <TABLENAME [sql:id="value"] col="value" col="value"?../>
 </sql:before>
```

```
 <sql:after>
    <TABLENAME [sql:id="value"] [sql:at-identity="value"]
      col="value" col="value"?../>
 </sql:after>
</sql:sync>
```

or

```
<sql:sync xmlns:sql="xml-sql">
        <sql:before>
                <TABLENAME [sql:id="value"]>
                   <col>"value"</col>
                   <col>"value"</col>
                   ...
                </TABLENAME>
                ...
        </sql:before>
        <sql:after>
                <TABLENAME [sql:id="value"] [sql:at-identity="value"]>
                   <col>"value"</col>
                   <col>"value"</col>
                   ...
                </TABLENAME>
                ...
        </sql:after>
</sql:sync>
```

15.5.2. Elements Description

The *<sync>* tag of the updategram signifies the beginning of an operation(s) The rows specified in the *<before>* refer to existing records in the database. The rows specified in the *<after>* block refer to what the user wants in the database. *<TABLENAME.../>* identifies target table.

The *sql:at-identity* attribute stores the last identity value added by the system (if possible). This identity value can then be used in subsequent operations.

The *sql:id* attribute is used to mark rows. This forces an association between the record specified in the *<before>* and *<after>* block in the update gram. When there are multiple instances specified, it is recommended that *sql:id* attribute be used for all the instances.

Each *<TABLENAME.../>* refers to a single table. Multiple *<TABLENAME.../>* entries are allowed in the same *<before>* or *<after>* tags, or in both *<before>* and *<after>* tags; however, nesting is not allowed. The *<before>* and *<after>* tags are optional. A missing tag is the same as having a tag with no content.

15.5.3. Determining Actions

If only the *<after>* block is specified, the rows specified in the *<after>* block are inserted in the table(s). If both the *<before>* and *<after>* blocks are specified, then rows specified in the *<after>* block for which there are no corresponding rows in the *<before>* block are inserted in the table(s).

In an update operation, the rows specified in the *<before>* block refer to existing rows in the database. The corresponding rows in the *<after>* block reflect what the user wants in the database. A row update operation is performed if there is a row in both the *<before>* and *<after>* sections with the same set of values for the attributes that uniquely identify a row in a table. Rows specified in the *<before>* block must be valid in the database for the updategram to successfully update the rows.

In a delete operation, if only the *<before>* block is specified in the update gram, the rows specified in the *<before>* block are deleted from the table(s). If both the *<before>* and *<after>* blocks are specified, the rows for which there are no corresponding rows in the *<after>* block are deleted from the table(s).

15.5.4. Using Input Parameters

Parameters declarations should be described in the <header> section of the updategram. There should be one *<param>* row for each parameter.

General syntax:

```
<sql:header xmlns:sql="xml-sql">
  <sql:param name="PARAM_NAME" [default="DEFAULT_VALUE"]/>
  ...
</sql:header>
```

Where *PARAM_NAME* is the name of the parameter and *DEFAULT_VALUE* is optional default of parameter Parameters in updategram should have *$PARAM_NAME* instead of a value. On processing, Virtuoso replaces *$PARAM_NAME* with the corresponding value from the *<input_parameters>* given to the function `xmlsql_update()` .

15.5.5. Examples

Given the following tables:

```
CREATE TABLE Orders (
    OrderID int identity,
    CustomerID varchar(10),
    EmpID int,
    PRIMARY KEY (OrderID));

CREATE TABLE OrderDetails (
    OrderID int,
    ProductID int,
    Quantity int);
```

A. Update Gram to Insert a Record

```
xmlsql_update (xml_tree_doc (xml_tree (
'<ROOT xmlns:sql="urn:schemas-microsoft-com:xml-sql">
<sql:sync>
  <sql:after>
    <Orders CustomerID="TEST" EmpID="99"/>
  </sql:after>
</sql:sync>
</ROOT>')));
```

B. Updategram with an *at-identity* Attribute

```
xmlsql_update (xml_tree_doc (xml_tree (
'<ROOT xmlns:sql="urn:schemas-microsoft-com:xml-sql">
<sql:sync>
  <sql:after>
    <Orders sql:at-identity="x" CustomerID="VINET" EmpID="10"/>
      <OrderDetails OrderID="x" ProductID="1" Quantity="50"/>
      <OrderDetails OrderID="x" ProductID="2" Quantity="20"/>
    <Orders sql:at-identity="x" CustomerID="HANAR" EmpID="11"/>
      <OrderDetails OrderID="x" ProductID="1" Quantity="30"/>
      <OrderDetails OrderID="x" ProductID="4" Quantity="25"/>
  </sql:after>
</sql:sync>
</ROOT>')));
```

C. Updategram to Delete a Record

```
xmlsql_update (xml_tree_doc (xml_tree (
'<ROOT xmlns:sql="urn:schemas-microsoft-com:xml-sql">
<sql:sync>
  <sql:before>
    <Orders CustomerID="HANAR" EmpID="11"/>
  </sql:before>
</sql:sync>
</ROOT>')));
```

D. Updategram to Update a Record

```
xmlsql_update (xml_tree_doc (xml_tree (
'<ROOT xmlns:sql="urn:schemas-microsoft-com:xml-sql">
<sql:sync>
```

```
  <sql:before>
    <Orders sql:id="1" CustomerID="VINET" EmpID="10"/>
  </sql:before>
  <sql:after>
    <Orders sql:id="1" CustomerID="VINET_NEW" EmpID="11"/>
  </sql:after>
</sql:sync>
</ROOT>')));
```

E: Using a different syntax for updategrams - entities in place of attributes - example D can be transformed to:

```
xmlsql_update (xml_tree_doc (xml_tree (
'<ROOT xmlns:sql="urn:schemas-microsoft-com:xml-sql">
<sql:sync>
  <sql:before>
    <Orders sql:id="1">
      <CustomerID>VINET</CustomerID>
      <EmpID>10</EmpID>
    </Orders>
  </sql:before>
  <sql:after>
    <Orders sql:id="1">
      <CustomerID>VINET_NEW</CustomerID>
      <EmpID>11</EmpID>
    </Orders>
  </sql:after>
</sql:sync>
</ROOT>')));
```

Note that two syntaxes cannot be mixed in one document.

F: Using input parameters

Assume the following table:

```
CREATE TABLE Shippers(
  ShipperID INTEGER,
  CompanyName VARCHAR(40),
  Phone VARCHAR(24),
  PRIMARY KEY (ShipperID));

xmlsql_update (xml_tree_doc (xml_tree (
'<DocumentElement xmlns:sql="urn:schemas-microsoft-com:xml-sql">
    <sql:header>
      <sql:param name="ShipperID" default="2"/>
      <sql:param name="CompanyName" default="United Package New"/>
      <sql:param name="Phone" default="(503) 555-3199 (new)"/>
    </sql:header>
    <sql:sync>
        <sql:before>
        </sql:before>
        <sql:after>
            <Shippers sql:id="1" ShipperID="\$ShipperID"
            CompanyName="\$CompanyName" Phone="\$Phone"/>
        </sql:after>
    </sql:sync>
</DocumentElement>')),
    vector ('ShipperID','10','CompanyName','DHL','Phone','+359 32 144'));
                -- <- this is a array with input parameters
```

This will add one record to the Shippers table with the data in the array. Note that the slash/dollar sign pair '\$' transforms to dollar sign '$' only

15.6. XML Templates

Virtuoso XML templates allow execution of queries over HTTP in order to achieve any combination of the following:

Execution of SQL queries returned in an XML formatted resultset.

Execution of XQuery and XPath queries against XML and SQL-XML documents in the Virtuoso WebDAV repository.

Use an XML notation (Updategrams) to insert/update/delete SQL data.

An XML template is an XML file containing a query, optional parameters with default values for the query, a place to specify an XSL stylesheet, and a section for specifying updatagram based synchronization metrics. They are meant to be executed as an XML described short-cut to an query result, an XML document. The XML document returned from calling an XML template can be served raw, or transformed using XSLT.

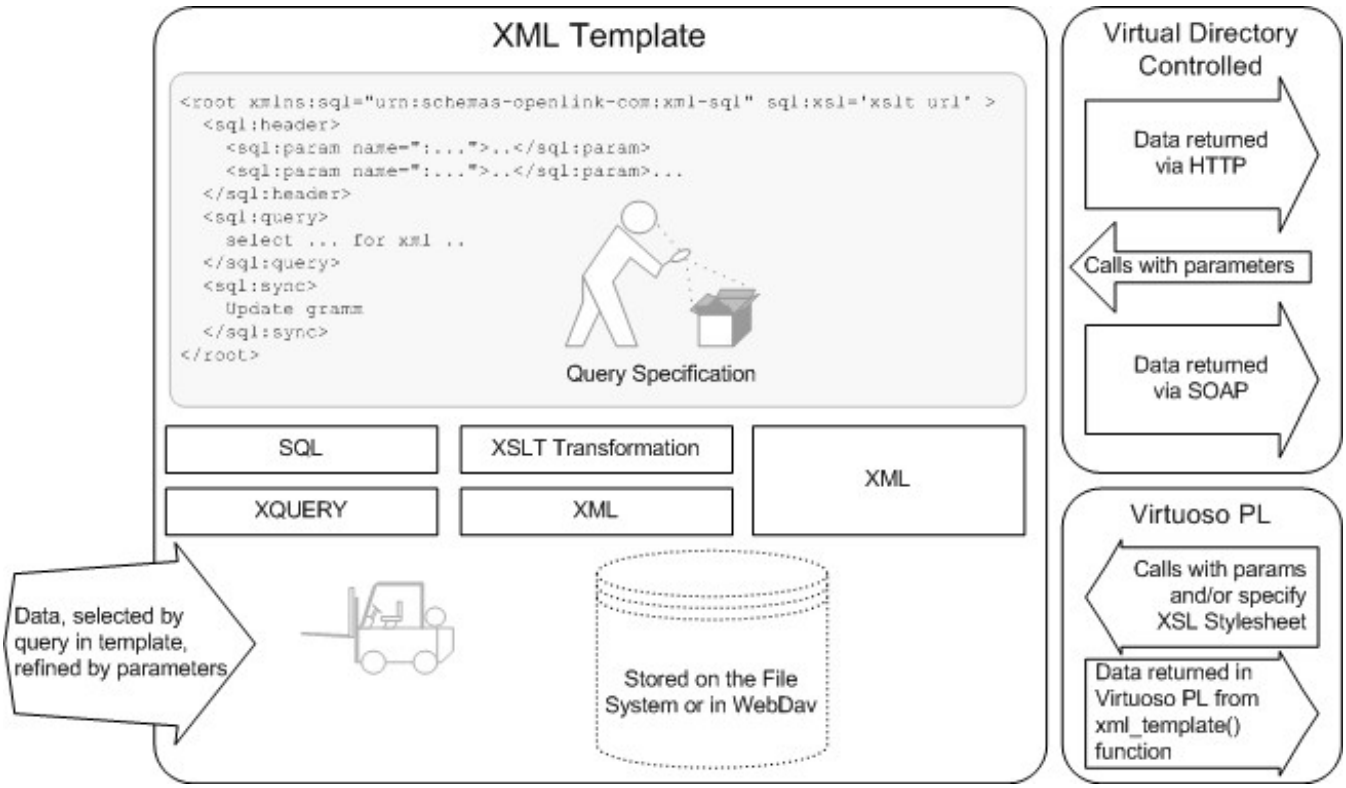
XML templates can be executed from within Virtuoso procedure language using the `xml_template()` function, or published as SOAP compliant XML Web Services, which makes them accessible to any SOAP and WSDL aware environment.

XML templates provide quick easy access to results from a SQL query as usual, but now this can be saved to a file. The results are not saved, just the query definition. You can use this feature to rapidly produce dynamic reports that can potentially be rendered in different ways by providing an alternate stylesheet. The report can be refined on the fly by providing parameters for the query. The output is reachable via HTTP directly by providing the URL to the template.

When XML templates are executed via HTTP, the XSLT transformation will be performed automatically if the "sql:xsl" attribute is specified in the templates root element. This means that the default XSLT transformation cannot be avoided if the template is executed over HTTP. However, you have the option whether to apply the transformation or not when using the `xml_template()` function. XML templates containing <sql:query> elements return either results or messages regarding the queries. An XSLT transformation can be made on the result from `xml_template()` using the returned XSLT sheet URL. Hence it is conditional in PL programming. The application developers can choose to either use the style sheet specified in the template, use another style sheet, or skip XSLT transformation entirely. This feature provides full flexibility for the procedure developer.

XML templates are intended for execution over HTTP. The template file can be stored either on the file system, WebDAV repository or stored on another HTTP server being referenced by a URL parameter. Specifying a template as a URL parameter naturally introduces a new potential security risk associated with the template owners web server.

Figure 15.1. Conceptual View of XML Templates



Queries and updategrams can be parameterized. The parameters must be defined in the header element, which consists of zero or more param elements. The default value of the parameter is enclosed within the param element whose values are typically replaced during the execution phases. When XML templates are executed from the `xml_template()` function the parameters are specified in a vector as an input parameter. When XML templates are executed via HTTP the parameters are contained in the URL.

Important

All <sql:param> parameter definitions in the template for SQL queries need to be named parameters, and the names must be preceded by a colon i.e. :ParamName (note colon at the front)
. The colon is not required for updategrams.

If an error occurs as a result of executing a SQL query or updategram, the comment will be included in the result detailing the error. The subsequent queries and updategrams will still be executed.

See Also:

The Exposing Persistent Stored Modules as Web Services section as this also describes how XML Templates can be published to web services as a SOAP messages using a PL Wrapper. This is achieved using the Administrative Interface.

`xml_template()`

15.6.1. Syntax

The format of an XML template is shown below, illustrating how SQL queries and updategrams are specified:

```
<root xmlns:sql="urn:schemas-openlink-com:xml-sql" sql:xsl='xslt url' >
  <sql:header>
    <sql:param name=":...">..</sql:param>
    <sql:param name=":...">..</sql:param>...
  </sql:header>
  <sql:query>
    select ... for xml ..
  </sql:query>
  <sql:sync>
    Update gramm
  </sql:sync>
</root>
```

The root element can contain two attributes. The first is the required namespace declaration of xmlns:sql="urn:schemas-openlink-com:xml-sql", required to identify the XML as an XML template. The second attribute allows the specification of an optional XSLT stylesheet to be applied to the resulting XML document, if applicable. The XSLT stylesheet file can be specified as either a relative or absolute URL.

The following elements can be defined in the "sql" namespace for an XML Template:

- The

  "root"

  tag can be any name, its purpose is to provide the top-level element required for any well-formed XML, and provides the root element for the resulting XML document, if any.
- <*sql:header*>

  This tag is used to hold the parameters for templates execution such as <sql:param> elements. The <sql:header> element allow us to define multiple parameters.
- <*sql:param*>

  This element is used to define a named parameter that is passed to the query and/or updategram inside the template. Each <xsl:param> element defines one parameter. Multiple <xsl:param> elements can be specified within the <sql:header> element.
- <*sql:query*>

  This element is used to specify SQL/XML queries. It is possible to specify multiple <sql:query> elements within a single template.
- <*sql:sync*>

  This element is used to contain updategrams.

<sql:query> and <sql:sync> entries are executed sequentially in the order they appear as separate transactions. Therefore, if you have multiple <sql:query> or <sql:sync> elements in the template, if one fails, the others will proceed.

XML templates can be executed directly from Virtuoso PL using the `xml_template()` function.

To allow XML template execution from a Virtuoso virtual directory and it's descendants the special option: 'xml_templates' must be used in the virtual directory definition. This option can be set from the Conductor / Web Application Server / Virtual Domains & Directories or from SQL (or ISQL) using the `vhost_define(.... , opts=>vector('xml_templates', 'yes'));` function. In the usual way, the SQL user specified for VSP execution within the virtual directory definition will be used for executing the templates within such web directories. If your XML Templates are to run from a DAV directory then you must allow suitable execute permissions for the file and directory.

When a virtual directory is configured to allow execution of XML templates be aware that this also means that descendant directories inherit this property. Also be aware that this also allows execution of VSP files in the normal way. WebDAV also has another layer of security attributes that will need to be set to enable files to be executable. By default files in DAV do not have execute privileges.

Explicitly specifying "contenttype=text/html" as a URL parameter will instruct the Virtuoso HTTP server to return the HTML output.

UpdateGrams .

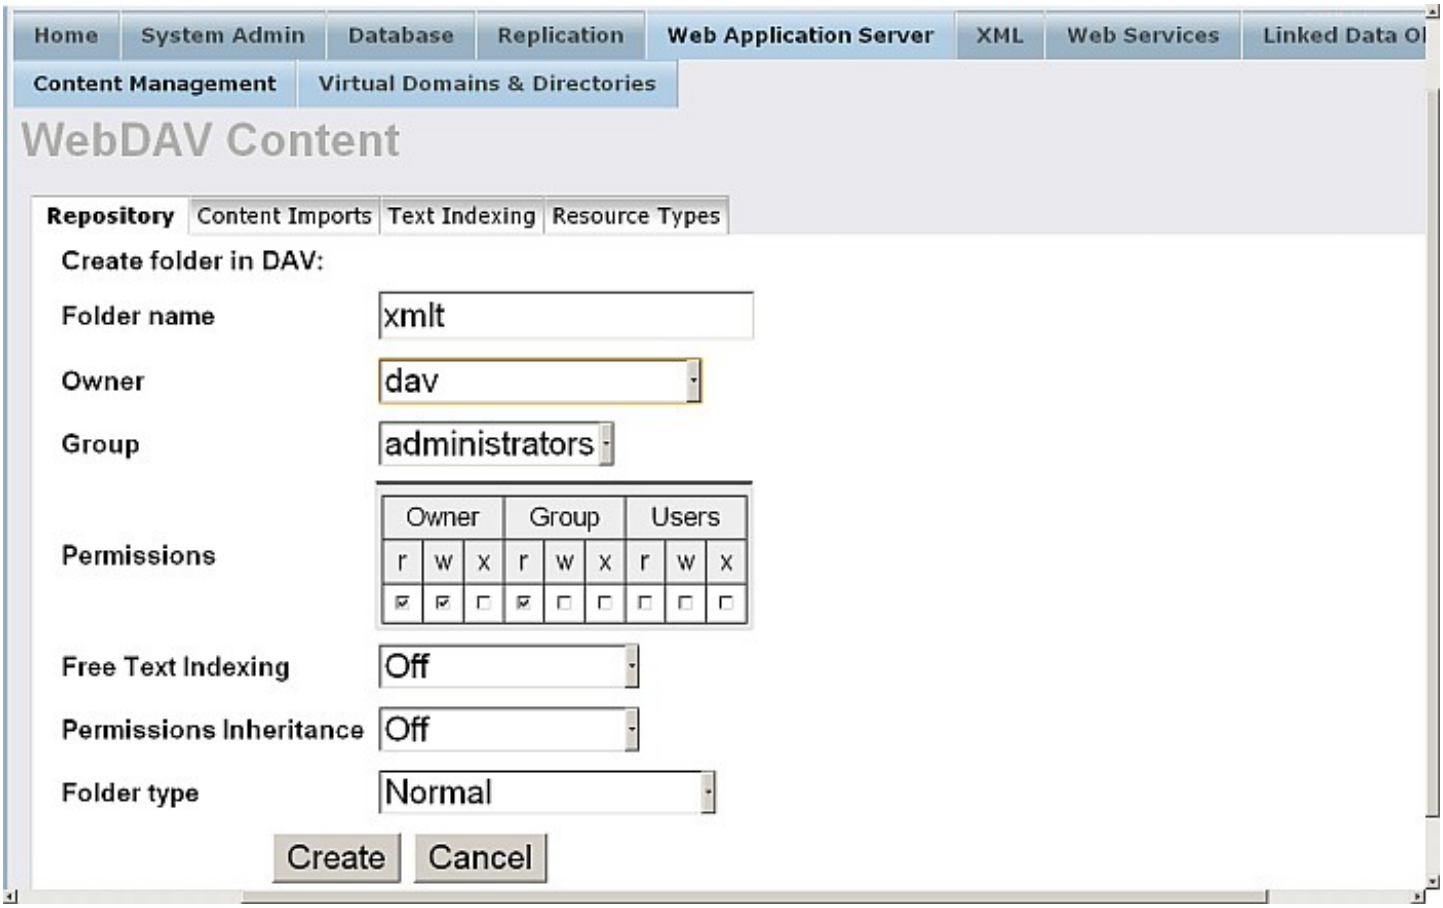
The FOR XML clause .

15.6.2. Saving SQL Queries to XML Template

Using the Conductor Administration Interface, we are going to make and save a query to an XML template in WebDav, and then demonstration its use from a browser.

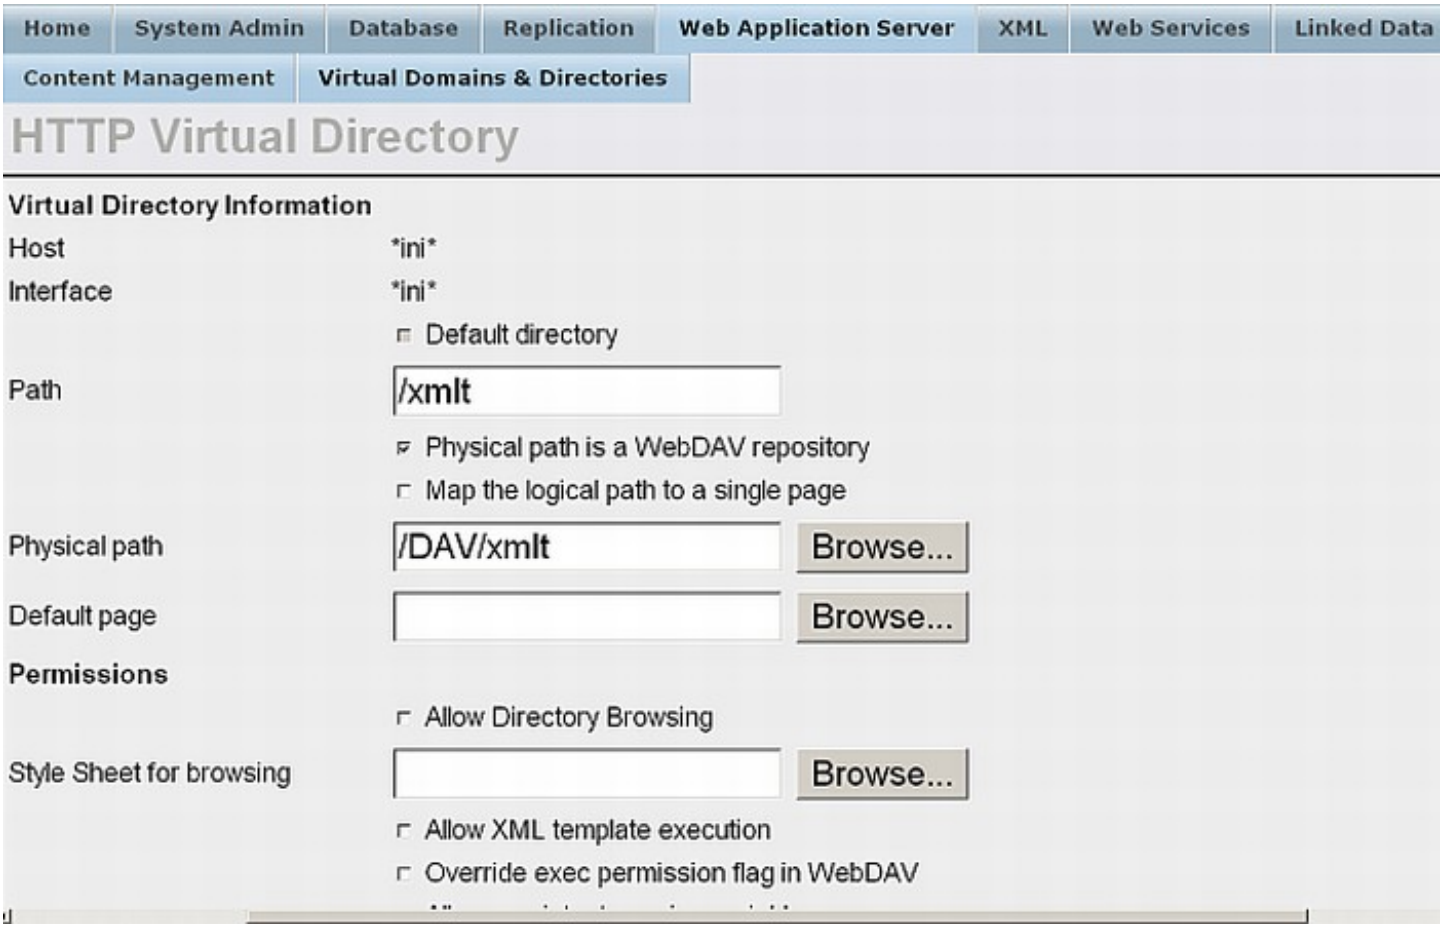
First we will make a new WebDAV directory. From Web Application Server -> Content Management -> Repository click the "New folder" icon and in the shown form enter for "Folder Name": xmlt. Choose for "Owner" dav and click the "Create" button.

Figure 15.2. Creating a new directory (collection) in WebDAV



Next we need to configure a virtual directory mapping to this so that XML Templates can be executed later. Go to Web Application Server / Virtual Domains & Directories and for your {Default Web Site} click the link "New Directory". In the shown form click "Next".

Figure 15.3. Configuring a Virtual Directory to respond to XML Template requests from our Dav



The programmatic equivalent for creating a virtual directory is the command in iSQL:

```
SQL>vhost_define(lpath=>'/DAV/xmlt',
                 ppath=>'/DAV/xmlt/',
                 is_dav=>1,
                 vsp_user=>'demo',
                 opts=>vector('xml_templates', 'yes'));
```

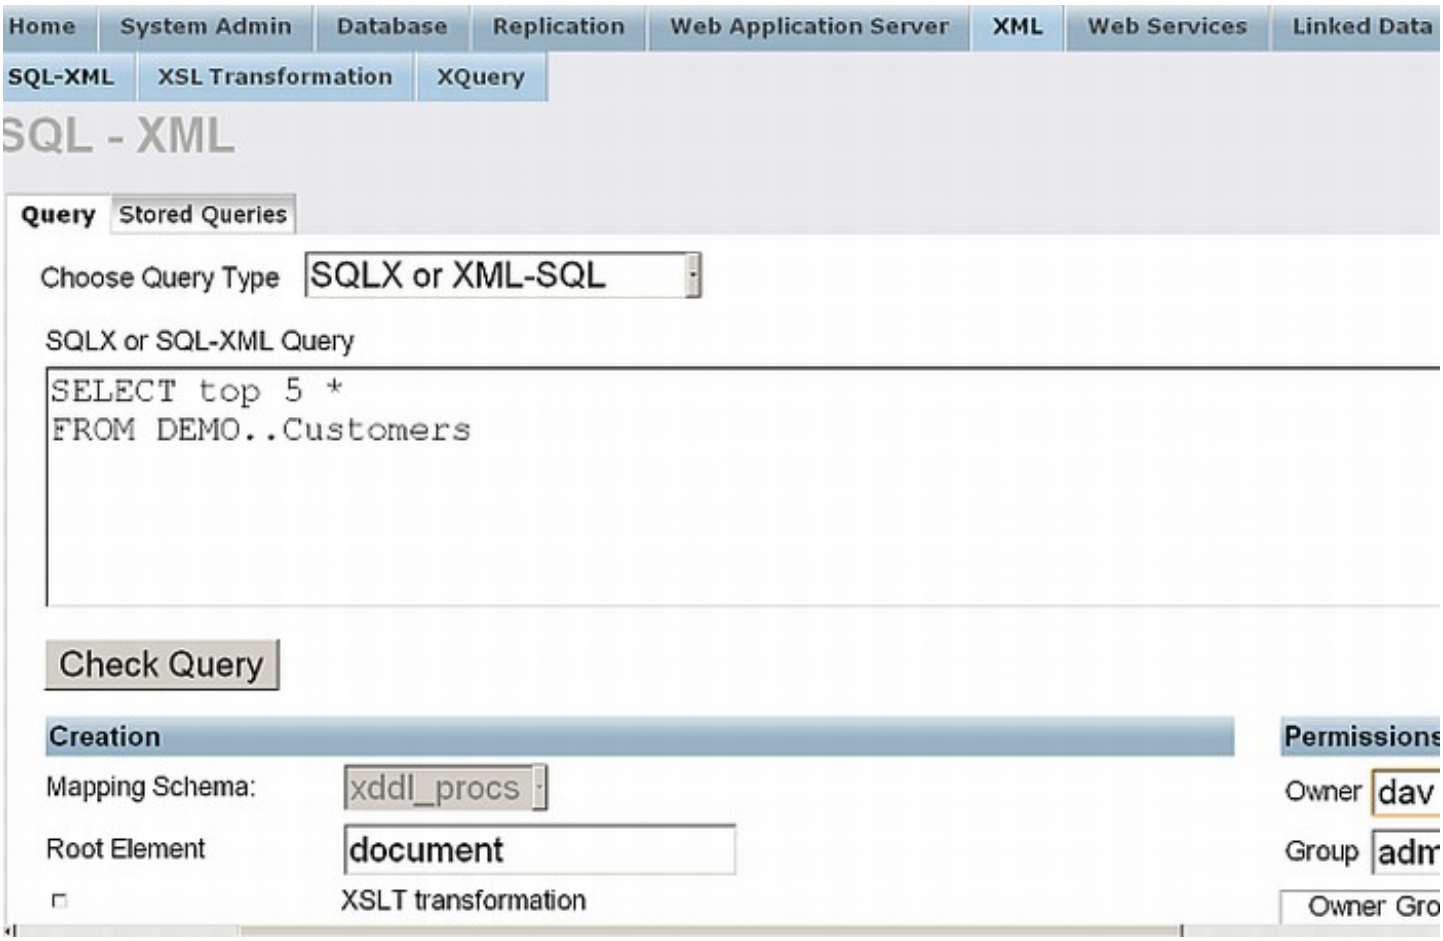
Now we go to Database/Interactive SQL and will use a simple query. Here we are assuming that the Demo database is being used, so we will query the Customers table:

Figure 15.4. A SQL Query

Figure 15.5. Results

Now go to XML -> SQL-XML and enter in the query area the sql statement from above. Here we can supply some "FOR XML" clause, "FOR XML AUTO" being the simplest. Enter in the field "WebDAV resource path for the result" the directory we created earlier, i.e. it should be /DAV/xmlt and add the name of the xmltemplate to which the result will be saved, for example: sql-template.xml So finally the value should be `/DAV/xmlt/sql-template.xml` .

Figure 15.6. The Save XML Template page and settings



Once the template has been saved we can test it. Point your browser at you newly created file, a URL similar to: `http://host:port/DAV/xmlt/sql-template.xml` :

Figure 15.7. The test results: http://host:port/DAV/xmlt/sql-template.xml

```
<?xml version="1.0" encoding="ISO-8859-1" ?>
- <document>
  <Customers CustomerID="ALFKI" CompanyName="Alfreds Futterkiste" ContactName="Maria Anders" ContactTitle="Sales
    Representative" Address="Obere Str. 57" City="Berlin" Region="" PostalCode="12209" Country="Germany" CountryCode="gm"
    Phone="030-0074321" Fax="030-0076545" ROWGUID="CD83B720-1FEC-11DC-8A76-D44C76F22C3E" />
  <Customers CustomerID="ANATR" CompanyName="Ana Trujillo Emparedados y helados" ContactName="Ana Trujillo"
    ContactTitle="Owner" Address="Avda. de la Constitución 2222" City="México D.F." Region="" PostalCode="05021" Country="Mexico"
    CountryCode="mx" Phone="(5) 555-4729" Fax="(5) 555-3745" ROWGUID="CD853E50-1FEC-11DC-8A76-D44C76F22C3E" />
  <Customers CustomerID="ANTON" CompanyName="Antonio Moreno Taquería" ContactName="Antonio Moreno" ContactTitle="Owner"
    Address="Mataderos 2312" City="México D.F." Region="" PostalCode="05023" Country="Mexico" CountryCode="mx" Phone="(5) 555-
    3932" Fax="" ROWGUID="CD853E51-1FEC-11DC-8A76-D44C76F22C3E" />
  <Customers CustomerID="AROUT" CompanyName="Around the Horn" ContactName="Thomas Hardy" ContactTitle="Sales

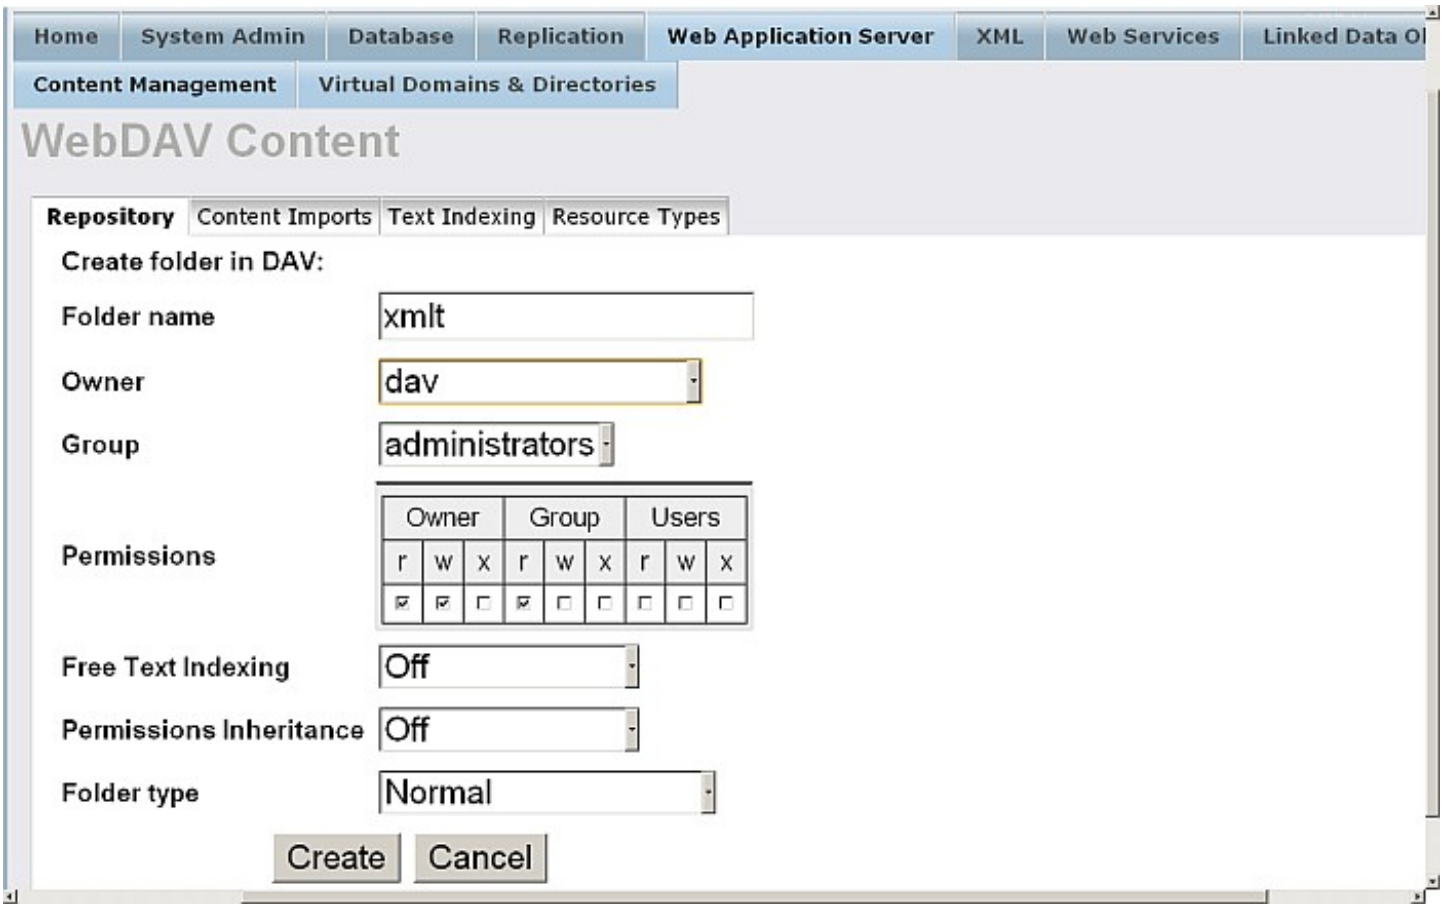
Exposing XML Templates as Web Services .

15.6.3. Saving XQUERY Queries to XML Template

Using the Conductor Administration Interface, we are going to make and save a query to an XML template in WebDav, and then demonstration its use from a browser.

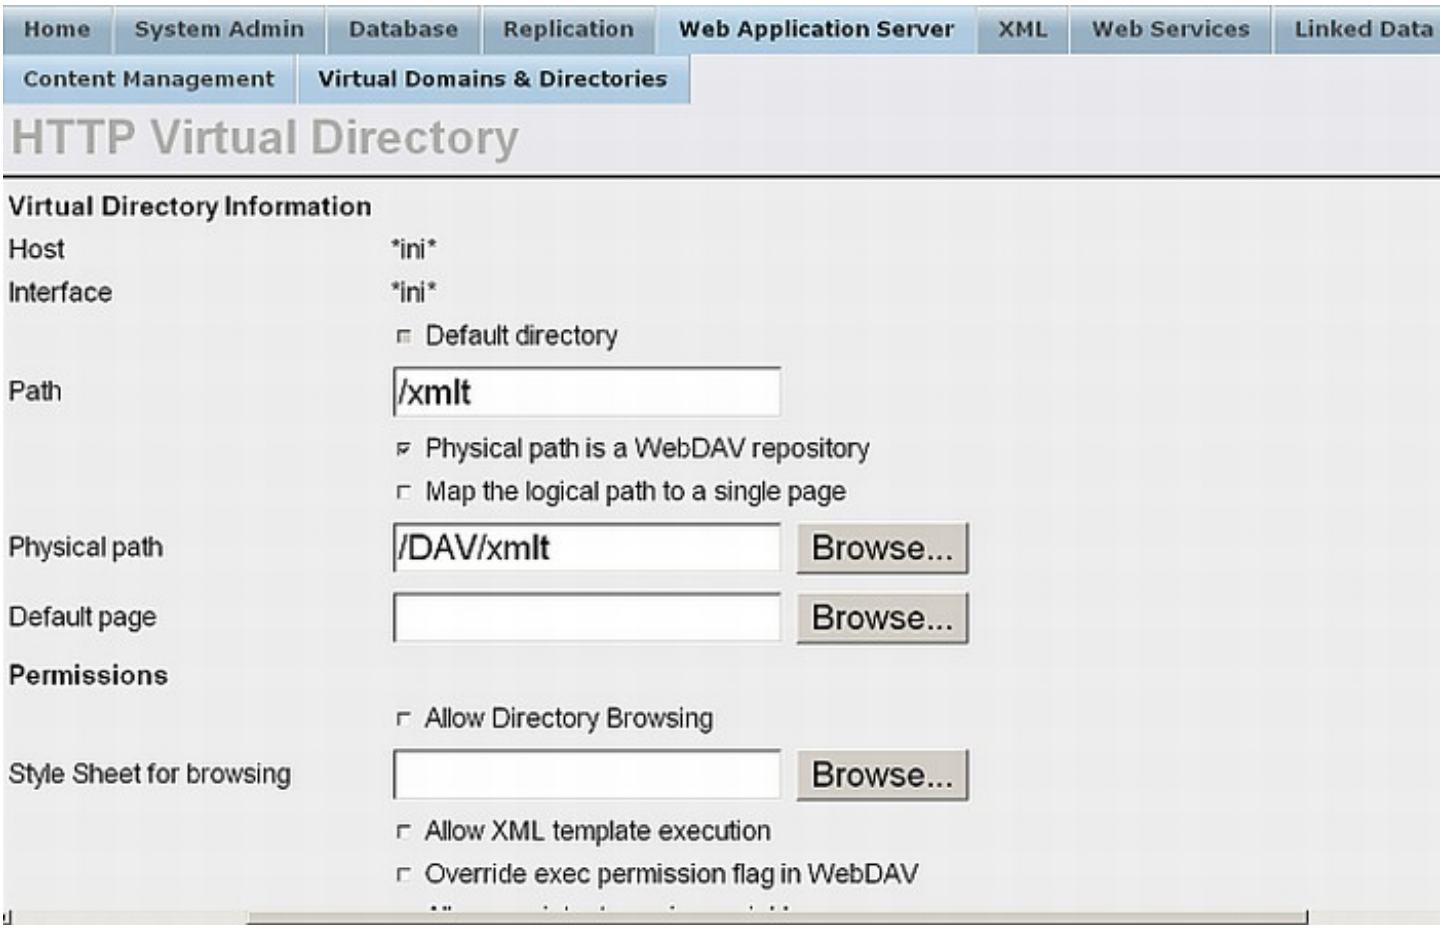
First we will make a new WebDAV directory. From Web Application Server -> Content Management -> Repository click the "New folder" icon and in the shown form enter for "Folder Name": xmlt. Choose for "Owner" dav and click the "Create" button.

Figure 15.8. Creating a new directory (collection) in WebDAV



Next we need to configure a virtual directory mapping to this so that XML Templates can be executed later. Go to Web Application Server / Virtual Domains & Directories and for your {Default Web Site} click the link "New Directory". In the shown form click "Next".

Figure 15.9. Configuring a Virtual Directory to respond to XML Template requests from our Dav



The programmatic equivalent for creating a virtual directory is the command in iSQL:

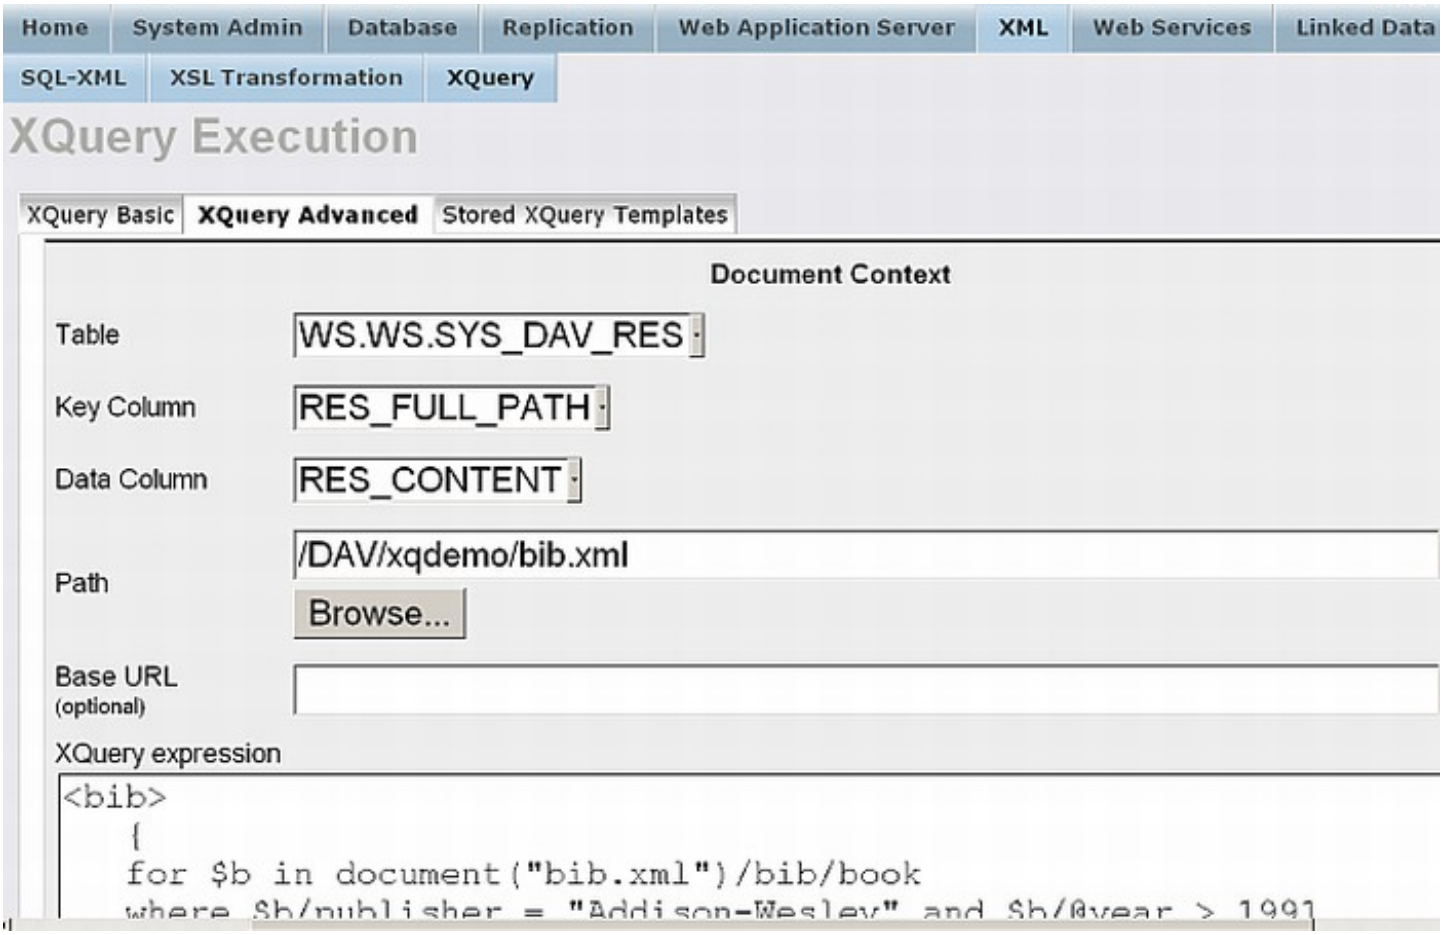
```
SQL>vhost_define(lpath=>'/DAV/xmlt',
                 ppath=>'/DAV/xmlt/',
                 is_dav=>1,
                 vsp_user=>'demo',
                 opts=>vector('xml_templates', 'yes'));
```

Now we go to XML -> XQuery -> XQuery Advanced.

We will start by testing the following query against the Demo database

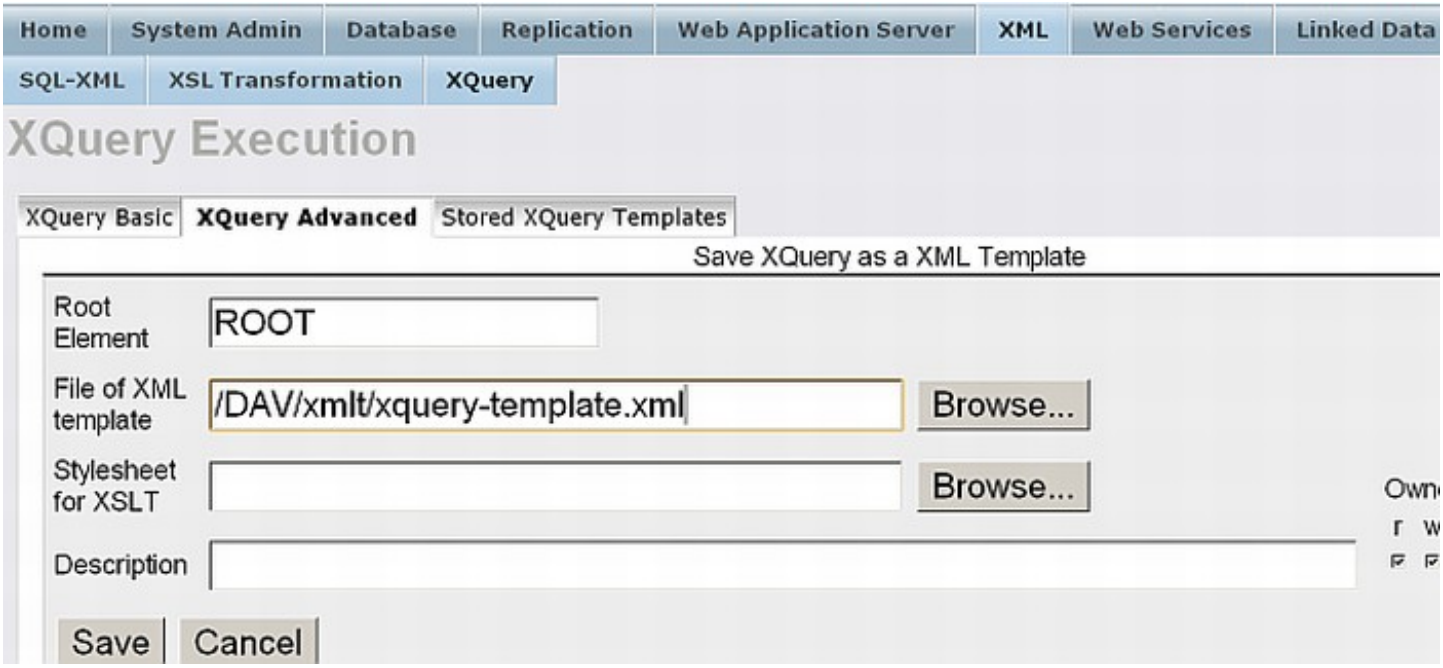
```
<bib>
   {
   for $b in document("bib.xml")/bib/book
   where $b/publisher = "Addison-Wesley" and $b/@year > 1991
   return
      <book year = {$b/@year}>
         {$b/title}
      </book>
   }
</bib>
```

Figure 15.10. XQUERY query against the Demo database



Now we will save this as an XML template by pressing the Save button. The query we used will be copied to the save XML template page. We will ensure that the name of the file is `/DAV/xmlt/xquery-template.xml` :

Figure 15.11. Saving the XML template for the Xquery query



See Also:

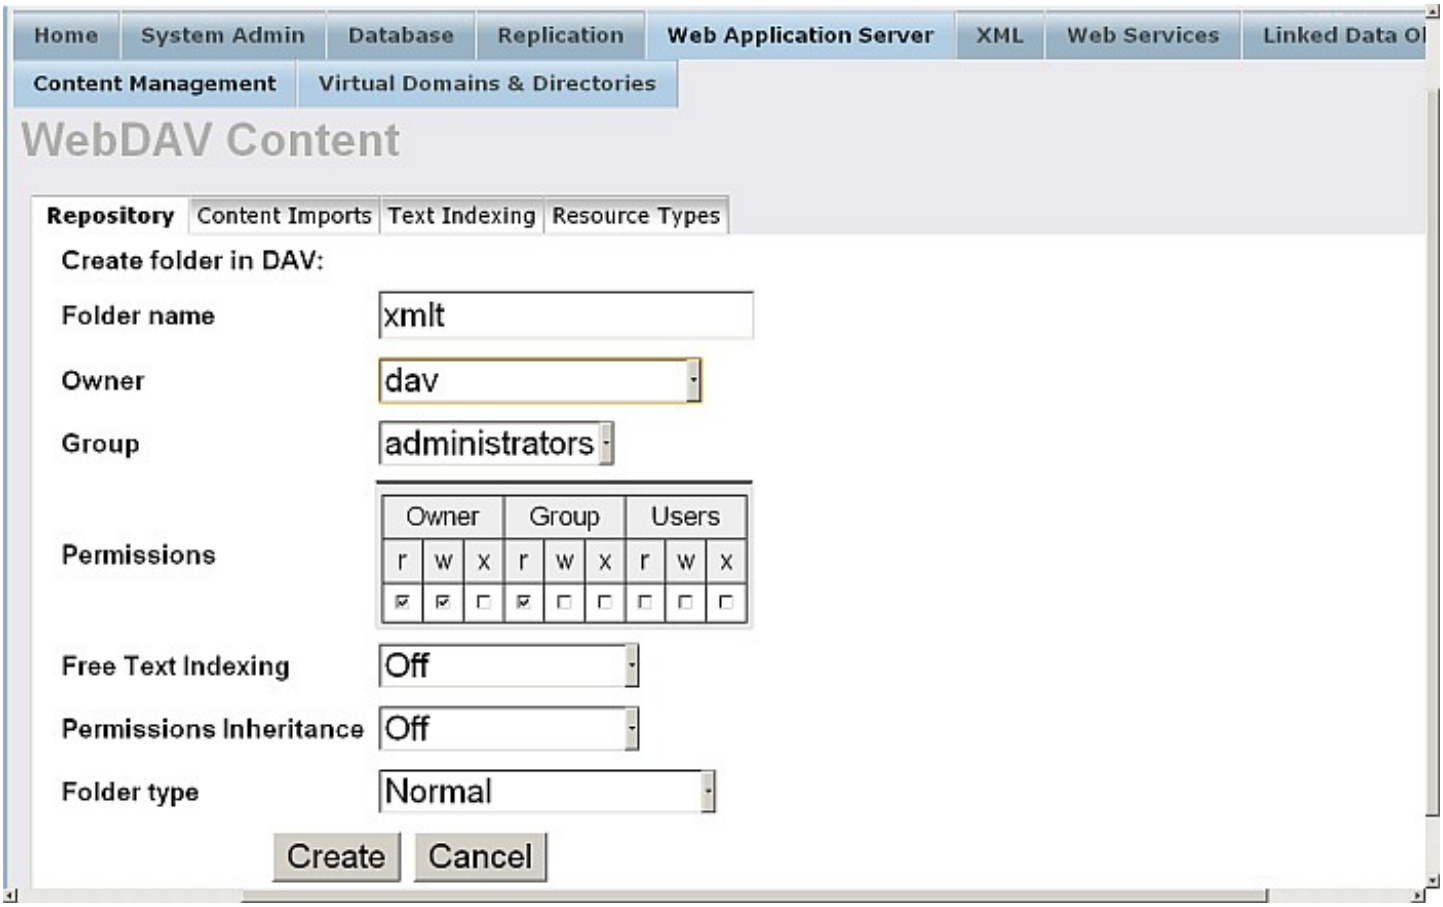
Exposing XML Templates as Web Services .

15.6.4. Saving XPATH Queries to XML Template

Using the Conductor Administration Interface, we are going to make and save a query to an XML template in WebDav, and then demonstration its use from a browser.

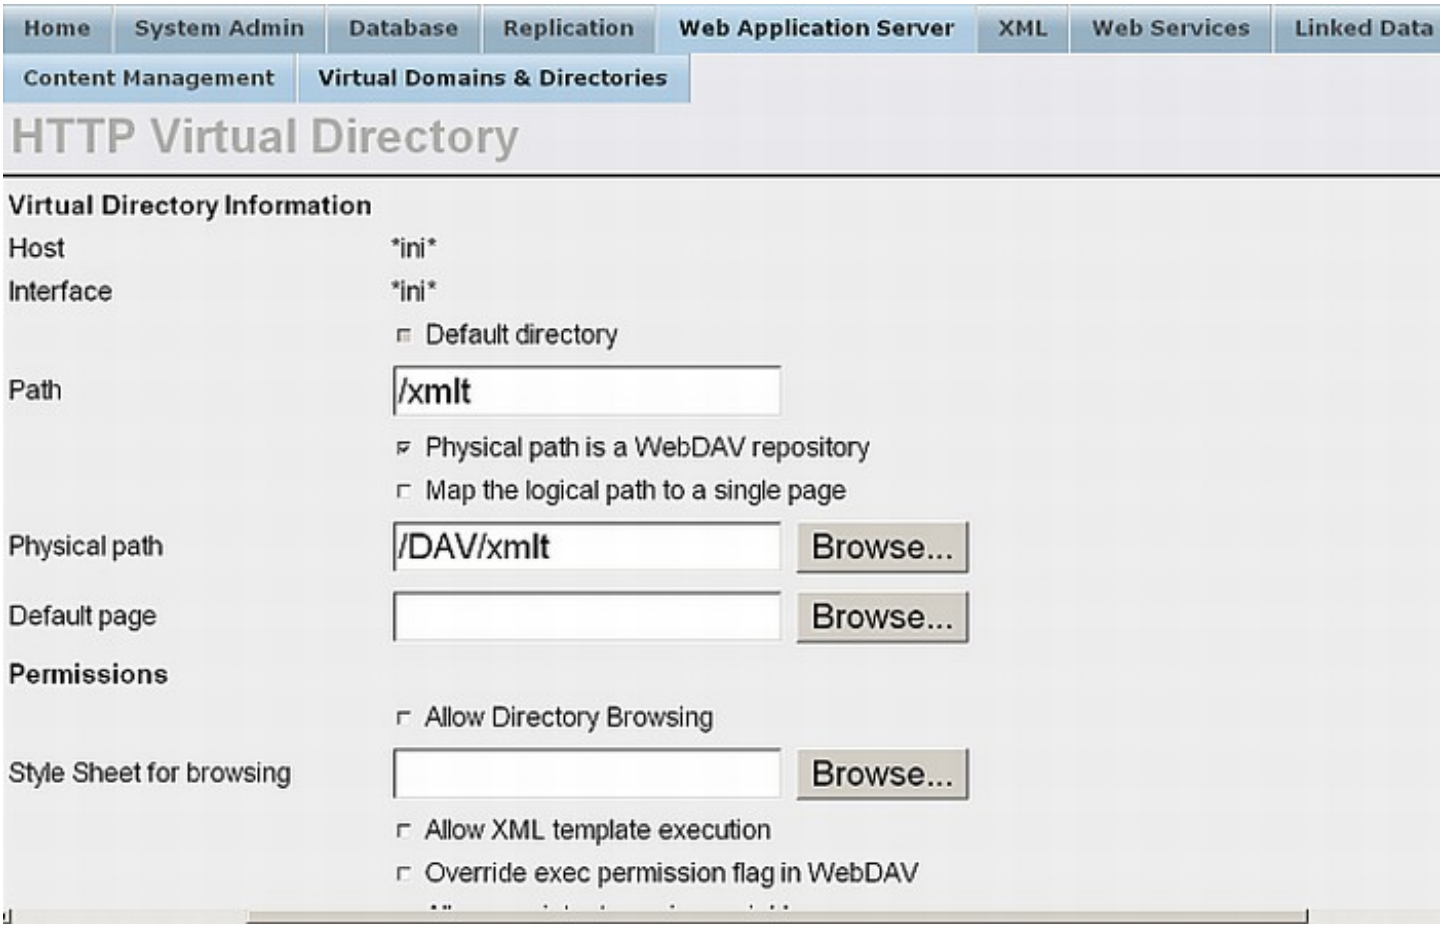
First we will make a new WebDAV directory. From Web Application Server -> Content Management -> Repository click the "New folder" icon and in the shown form enter for "Folder Name": xmlt. Choose for "Owner" dav and click the "Create" button.

Figure 15.12. Creating a new directory (collection) in WebDAV



Next we need to configure a virtual directory mapping to this so that XML Templates can be executed later. Go to Web Application Server -> Virtual Domains & Directories and for your {Default Web Site} click the link "New Directory". In the shown form click "Next":

Figure 15.13. Configuring a Virtual Directory to respond to XML Template requests from our Dav

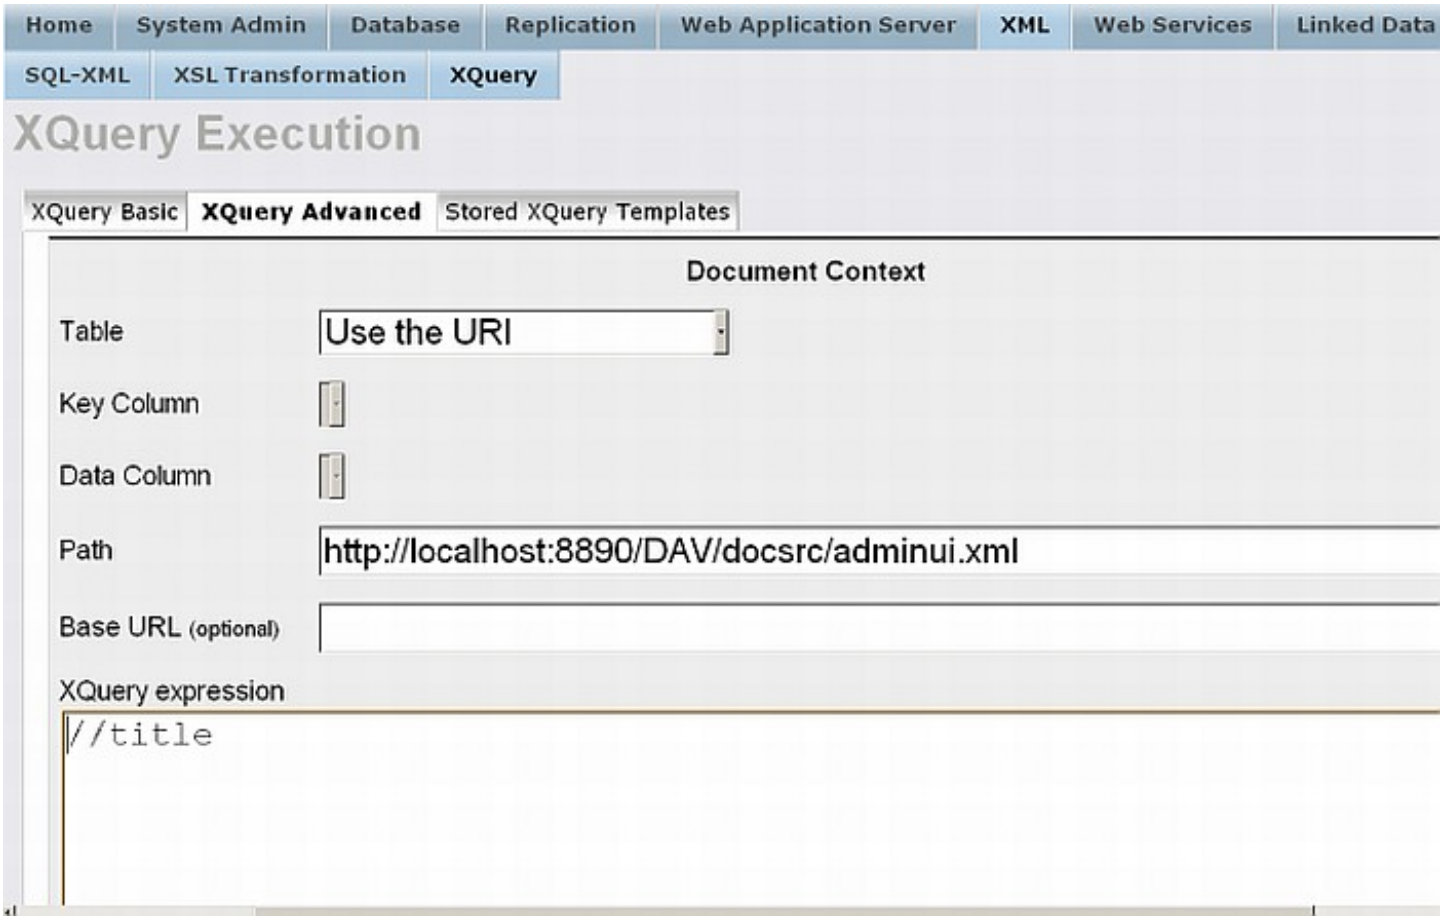


The programmatic equivalent for creating a virtual directory is the command in iSQL:

```
SQL>vhost_define(lpath=>'/DAV/xmlt',
                 ppath=>'/DAV/xmlt/',
                 is_dav=>1,
                 vsp_user=>'demo',
                 opts=>vector('xml_templates', 'yes'));
```

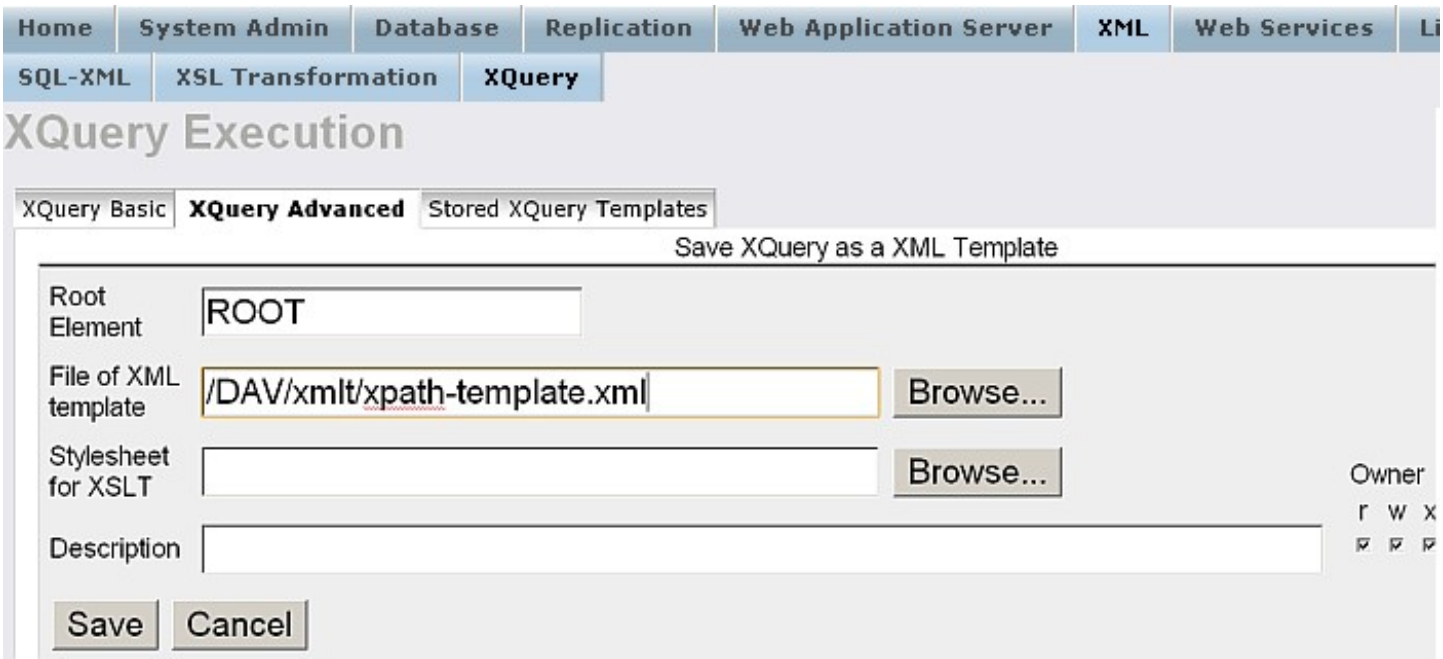
Now we set our sights on the XML files in WebDAV. We will perform a very simple XPATH query on an XML source file from this documentation. We will search for the existence of `<title>` tags in `http://host:port/DAV/docsrc/adminui.xml`:

Figure 15.14. XPATH query on a file in WebDAV



Make a quick mental note of the trivial result. Now we will save our query as an XML template to be executed over HTTP. Pressing the Save button takes us to the save XML Template page. We ensure that the file to save is set to `/DAV/xmlt/xpath-template.xml`:

Figure 15.15.



Once our query has been saved in an XML template we can test it by pointing a web browser at the URL for the file as we configured our virtual directory for, which will be similar to: `http://example.com/DAV/xmlt/xpath-template.xml`:

Figure 15.16.

See Also:

Exposing XML Templates as Web Services .

15.6.5. Programmatic Examples

Example 15.19. Executing an XML template from the file system

First step is to setup the /xmlt directory on file system. The function `vhost_define()` will be used to enable execution of XML templates. DBA privileges are required to use this function:

```
SQL> vhost_define (lpath=>'/xmlt', ppath=>'/xmlt/',
  vsp_user=>'demo', opts=>vector('xml_templates', 'yes'));
```

Now the following files must be stored as: <www-root>/xmlt/file1.xml

```
<?xml version ='1.0' encoding='UTF-8'?>
 <root xmlns:sql='urn:schemas-openlink-com:xml-sql' sql:xsl='shippers.xsl'>
   <!-- XML template example -->

   <!-- parameters declaration -->

    <sql:header>
      <sql:param name=":ShipperID">2</sql:param>
      <sql:param name=":CompanyName">United Package (you should see me)</sql:param>
      <sql:param name=":Phone">(503) 555-3199</sql:param>
    </sql:header>
   <!-- XML updategram , this will update the second record -->

    <sql:sync>
        <sql:before>
            <Shippers sql:id="1" ShipperID=":ShipperID"/>
        </sql:before>
        <sql:after>
            <Shippers sql:id="1" ShipperID=":ShipperID" CompanyName=":CompanyName" Phone=":Phone"/>
        </sql:after>
    </sql:sync>
   <!-- make a parametrized query -->

   <sql:query>
      SELECT ShipperID, CompanyName,Phone FROM Shippers where ShipperID = :ShipperID FOR XML AUTO
   </sql:query>
   <!-- make an error to see what happens -->

   <sql:query>
      select * from NotExist for xml auto
   </sql:query>
</root>
```

Now we want an XSL stylesheet stored as: <www-root>/xmlt/shippers.xslt containing the following:

```
<?xml version="1.0"?>

<xsl:stylesheet
    version="1.0"
    xmlns:xsl="http://www.w3.org/1999/XSL/Transform">
    <xsl:output method="html" indent="yes" />

  <xsl:template match="/">
        <html>
            <head>
            <title>Shippers list</title>
            </head>
            <body>
            <xsl:apply-templates/>
            </body>
        </html>
    </xsl:template>

  <xsl:template match="root">
        <table>
            <tr><td>ID</td><td>Name</td><td>Phone</td></tr>
            <xsl:apply-templates/>
        </table>
    </xsl:template>

  <xsl:template match="Shippers">
        <tr>
            <td><xsl:value-of select="@ShipperID"/></td>
            <td><xsl:value-of select="@CompanyName"/></td>
            <td><xsl:value-of select="@Phone"/></td>
        </tr>
    </xsl:template>
</xsl:stylesheet>
```

Point your web browser to:

```
http://[host:port]/xmlt/file1.xml
```

and then at:

```
http://[host:port]/xmlt/file1.xml?:ShipperID=3
```

for the results.

Example 15.20. Executing an XML template from WebDAV

The first step is to create a new DAV collection and configure it to allow XML template execution. DBA privileges are required for these operations. To create a DAV collection the function `dav_col_create()` can be used, followed by the `vhost_define()` function to allow XML template execution:

```
SQL> dav_col_create ('/DAV/xmlt/', '110100100', 'dav', 'dav', 'dav', 'dav');

SQL> vhost_define (lpath=>'/DAV/xmlt', ppath=>'/DAV/xmlt/',
  is_dav=>1, vsp_user=>'demo', opts=>vector('xml_templates', 'yes'));
```

Now, the file can be uploaded. The same file as in the previous example will be used, copied from the file system location to the DAV location: <www-root>/DAV/xmlt/file1.xml

```
SQL> dav_res_upload ('/DAV/xmlt/file1.xml',
  file_to_string (concat (http_root(), '/xmlt/file1.xml')), 'text/xml',
  '111101101N', 'dav', 'dav', 'dav', 'dav');
```

Likewise the XSLT stylesheet from the previous example will also be used in the same way, placing into the DAV location: <www-root>/DAV/xmlt/shippers.xslt

```
SQL> dav_res_upload ('/DAV/xmlt/shippers.xsl',
  file_to_string (concat (http_root(), '/xmlt/shippers.xsl')),
  'text/xsl', '110100100N', 'dav', 'dav', 'dav', 'dav');
```

This example can now be demonstrated by trying the following URLs in your web browser:

```
http://[host:port]/DAV/xmlt/file1.xml
```

and

```
http://[host:port]/DAV/xmlt/file1.xml?:ShipperID=3
```

15.7. XML DTD and XML Schemas

15.7.1. XML Document Type Definition (DTD)

It is always useful to store a description of an XML document inside the document itself. XML DTD is a set of directives to describe the structure of the document and references to other XML documents.

The XML parser of the Virtuoso Server can recognize and use most DTD directives.

If DTD describes the structure of the document (i.e. the allowed content of elements with particular names) then the XML parser can validate the source document in order to check if it matches to the rules written in the DTD.

If a DTD describes references to external XML entities then the parser can build either "standalone" or "non-standalone" internal representation. To build a "standalone" representation, the XML parser will retrieve all external resources and then it will replace every occurrence of every reference with a copy of the whole content of the resource. To build a "non-standalone" representation, XML parser remembers only referencing information but it tends to not retrieve external documents; they can be retrieved on demand later.

A DTD may describe some attributes as "unique identifiers" and as "references to unique identifiers". If requested, the XML parser can check that identifiers are really unique or that there are no "dangling" references to missing identifiers.

In an ideal world, source documents match the XML standard perfectly and all declared URIs are valid and can be accessed. The real application, however, should read inaccurate data and ignore some minor errors. To let the XML parser signal only errors that really can affect the application, it is possible to precisely configure the reaction of the parser on every sort of problem. In addition, the application can get a detailed human-readable log of diagnostic messages by calling `xml_validate_dtd()` to let user fix the document in question.

If an XML document contains a DTD then DTD is placed before any data nodes (if parts of DTD can be placed in separate documents then they will be retrieved before parsing data nodes). Thus XML parser has enough data to perform "DTD validation" of the source document right during the reading. It lets the parser provide detailed diagnostics with precise location of detected errors.

15.7.2. Configuration Options of the DTD Validator

If some built-in Virtuoso/PL or XPATH function can invoke XML parser then it is probably have a special argument to pass configuration options to the XML parser. The most typical value of such an argument is "configuration string" that is a sequence of pairs parameter=value, delimited by spaces. Instead of single string, it can be passed as a vector of strings of even length of sort

```
vector (parameter1, value1, parameter2, value2 ...)
```

. It can be NULL indicating that the parser can use default values. No errors are reported if a parameter is specified twice, in which case the last specified value will be used. The only exception is the 'Validation' parameter which sets typical values for all parameters; if it is specified then it should be the first parameter in the list. Both parameter names and values are case-insensitive.

Many parameters are used to specify the importance of a particular error. For a particular application some validity constraints may be much more important than others. Because less than perfectly valid XML is common in practice it is important to configure the validator to report only those errors which are relevant to the application. Using configuration parameters, one may specify "importance levels" for every group of problems. There are 5 "importance levels":

Table 15.1. Error Catch Levels

Error Level	Description
FATAL	violations must be reported and further processing of XML source must be terminated right after the term where the violation was detected, without checking for errors in the rest of the document
ERROR	violations must be reported and validation should continue to find further errors, but no XML document will be built if validation is invoked from such function as `xtree_doc()` or `xper_doc()`
WARNING	violations must be reported but XML processing will continue
IGNORE	validator must try to locate violations of given sort but only severe (possibly fatal) violations must be reported
DISABLE	the specified check must be turned off fully, saving time and maybe memory

Some parameters are just switches, with only two values available: 'ENABLE' and 'DISABLE'.

AttrCompletion (ENABLE/DISABLE, default is DISABLE). This is useful when DTD validator is invoked from XML parser. When enabled, the XML document built will contain default values of 'IMPLIED' attributes as if they present in source text. It may be useful if application should perform free-text search on all attribute values including defaults or if XML should be converted in form suitable for external non-validating XML processor or if given XML data should be stored later as part of composite document and composite document will have another DTD with other default values.

AttrMisFormat (FATAL/ERROR/WARNING/IGNORE/DISABLE, default is DISABLE). This describes how to report errors in syntax of values of attributes.

AttrUnknown (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report attributes whose names are not listed in the DTD.

BadRecursion (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report circular references, when replacement text of an entity contains reference to this entity again, either directly (e.g. '<!ENTITY bad "some &bad; replacement">) or through other entities (e.g. '<!ENTITY a "&b;"> '<!ENTITY b "&a;">).

BuildStandalone (ENABLE/DISABLE, default is DISABLE). When set to ENABLE, replacement texts of external entities will be inserted instead of references to these entities, thus all data from a composite document will be gathered together into one large XML. This is useful for checking the element content model of the whole document without breaks on references or if parsed XML will be passed to external application as a standalone document.

Fsa (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report violations of specified element-content model. Virtuoso's DTD validator contains a finite state automaton which can detect the first error in the content of some element, but remaining errors in the same element become "obscured" by the first one and will not be reported. Moreover, if element-content model is not SGML-compatible, some errors may remain undiscovered: it is possible to write a complex rule, so ambiguous that full check of all its interpretations will take prohibitively much time and memory. The validator will simplify such rules to make check faster, thus some errors will not be reported.

FsaBadWs (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report the most frequent violation of element-content model specified by DTD: the use of whitespace characters in positions where only elements are allowed, not PCDATA. It usually happens when XML is indented for readability. You may wish to specify 'FsaBadWs=IGNORE' to eliminate redundant messages about this violation. Note that if you will specify 'FsaBadWs=DISABLE' then you will disable the check of illegal PCDATA tokens for this particular case, so common rule for 'Fsa' violations will be applied and you will see messages.

FsaSgml (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report violations of SGML compatibility in element-content model. Some complex DTD rules for elements are not supported by SGML processors and the validator may report the use of such rules.

GeRedef (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report redundant definitions of generic entities. There redefinitions are errors in SGML but they may be ignored in XML processing. The first definition will be used and others will be ignored.

IdDuplicates (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report non-unique values of ID attributes. It is a data integrity error, because IDs are usually parts of some primary keys, and are expected to be unique.

IdrefIntegrity (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report "dangling references". Any value of IDREF attribute and any name from value of IDREFS attribute should appear in the same XML document as value of some ID attribute. You can think that an ID attribute specifies a hyperlink anchor and IDREF is a hyperlink, so it's a data integrity error if a hyperlink points to unknown location.

Include (FATAL/ERROR/WARNING/IGNORE/DISABLE). This configures reading of external sub-documents into "main" document you validate (and maybe load in database). If 'DISABLE', no additional documents will be read, otherwise external parameter-entities, external generic-entities and external DTD will be located, using their SYSTEM names. External documents may reside in file system, in database or in the Web. Absolute SYSTEM names (of form 'protocol://server/resource') will be used without any modifications, relative SYSTEM names should be "resolved", i.e. converted to absolute by adding a prefix from the *base_uri* argument of SQL function.

MaxErrors (a string that represents an integer from 1 to 10000, default is '25'). This specifies how many errors may be logged before the "Too many error messages" fatal error will be reported.

MaxWarnings (a string that represents an integer from 0 to 10000, default is '100'). This specifies how many warnings may be logged before the "Too many warning messages" event will stop their logging.

NamesUnknown (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report if the document contains element names which are not the declared in DTD. They may be typos in element names or signal that DTD is incomplete or obsolete. In addition, unknown names may be reported as element-content model violations.

NamesUnordered (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report element names not declared before use in DTD. Proper order ("declare element name before use it") is important solely for compatibility with SGML standard.

NamesUnresolved (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report if an element name used in the DTD is not declared at all. This may occur if DTD is incomplete or if some declaration in it are ignored conditional sections. Unresolved names cause no data integrity errors while remain unused in data section of the XML document, NamesUnknown parameter defines what happens if they're actually used.

PeRedef (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report redundant definitions of parameter entities. Similarly to redefinitions of generic entities, there redefinitions are errors in SGML but they may be ignored in XML processing. The first definition will be used and others will be ignored.

Sgml (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report violations of SGML compatibility. In fact, not all such violations are detected by the Virtuoso Server, because known SGML readers are insensitive to some sorts of violations.

TooManyWarns (FATAL/ERROR/WARNING/IGNORE/DISABLE). This describes how to report "Too many warning messages" event. While "Too many errors" is fatal error and terminates XML processing, "Too many warning messages" may have arbitrary "importance levels".

TraceLoading (ENABLE/DISABLE, default is DISABLE). If set to 'ENABLE', the validator will log every reading of any resource, for easier tracking of URI resolving problems. It's possible that some readings of sub-documents will not be reported: there's a limit for number of records in the log returned by the validator. In addition, sub-documents may be cached inside validator, so only first references to some sub-document will require reading procedure.

Validation (SGML/RIGOROUS/QUICK/DISABLE, default is DISABLE). This loads one of four "preset configurations". It must be the first parameter in configuration string, if used. DISABLE means "do not check for any type of error", QUICK is to check only for violation of "local" validity constraints, with disabled FsaBadWs, IdDuplicates and IdrefIntegrity, RIGOROUS enables these three groups, too, SGML enables all checks including all checks for SGML compatibility.

VcData (ENABLE/DISABLE, default is DISABLE). This describes how to report violations of generic validity constraints in data section of XML document. If constraint is not configured by other parameters listed here, it will be configured by this parameter (or by VcDtd if relates to the text of DTD section).

VcDtd (ENABLE/DISABLE, default is DISABLE). This describes how to report violations of generic validity constraints in DTD section of XML document. If constraint is not configured by other parameters listed here, it will be configured by this parameter (or by VcData if relates to the text of data section).

15.7.3. XML Schema Definition Language

The W3C XML Schema Definition Language is a way of describing and constraining the content of XML documents.

The XML Schema specification consists of three parts. One part defines a set of simple datatypes, which can be associated with XML element types and attributes; this allows XML software to do a better job of managing dates, numbers, and other special forms of information. The second part of the specification proposes methods for describing the structure and constraining the contents of XML documents, and defines the rules governing schema validation of documents. The third part is a primer that explains what schemas are, how they differ from DTDs, and how one builds a schema.

XML Schema introduces new levels of flexibility that may accelerate the adoption of XML for significant industrial use. For example, a schema author can build a schema that borrows from a previous schema, but overrides it where new unique features are needed. XML Schema allows the author to determine which parts of a document may be validated, or identify parts of a document where a schema may apply. XML Schema also provides a way for users of e-commerce systems to choose which XML Schema they use to validate elements in a given namespace, thus providing better assurance in e-commerce transactions and greater security against unauthorized changes to validation rules. Further, as XML Schema are XML documents themselves, they may be managed by XML authoring tools, or through XSLT. The implementation of XML Schema in Virtuoso is based on the W3C XML Schema Specification .

XML Schema Part-1: Structures

XML Schema Part-2: Datatypes

For parsing the schema definitions the DTD definition of XML Schema is used. This definition was taken from XML Schema Part-1: Structures .

15.7.4. XML Schema Functions

The Virtuoso interface to XML Schema is represented primarily by two functions:

`xml_validate_schema()`

`xml_load_schema_decl()`

The signature of the function `xml_validate_schema()` is the same as the function `xml_validate_dtd()` . It parses and validates an XML document. The root element of the document must contain the *`"schemaLocation"`* attribute with the value of the document's URI.

As described above, the XML Schema Processor implemented within Virtuoso relies on the XML Schema DTD, which is composed of two files: "XMLSchema.dtd" and "datatypes.dtd." These files must be placed in the system directory (see `xml_add_system_path()`).

The following XML Schema items are not fully implemented:

facets support is primitive;

you may only derive by restriction from the "anyType" type;

enumerations are not supported;

the "all" particle is not supported;

elements may not be defined within an element model group declaration;

unions are not supported;

"appinfo," "documentation," "list," and "notation" tags are ignored.

Virtuoso does not cache XML Schema documents; they are completely reprocessed every time the document is loaded.

15.7.5. XML Schema & SOAP

The XML Schema defines primitive types, such as "integer","string" and "float". Users may extend or restrict the primitive types to build their own type system. For example, a type "monthCode" could be an enumerated list of three character strings

corresponding to JAN, FEB, etc... SOAP types can use any of these types: native, primitive XML Schema types or complex types which should be fully described using XML Schema.

SOAP messages that use XML Schema types or complex types contain a fragment of XML Schema or a reference to a schema file so that the data types can be determined and messages validated.

The Virtuoso tutorials contain many examples from the SOAP Interop test suite. Each tutorial displays both the request message and response message from the server when the tests are executed. Below is a sample message exchange of the echoStruct tutorial (SO-S-20) which uses a trivial complex struct composed of an integer, float and a string:

Example 15.21. Sample Run of Tutorial SO-S-20

Struct parameter inputs:

```
varString = hello
varInt = 42
varFloat = 99.004997253418
```

Return value:

```
varString = hello
varInt = 42
varFloat = 99.004997253418
```

Request message:

```
<?xml version='1.0' ?>
<SOAP:Envelope
    SOAP:encodingType='http://schemas.xmlsoap.org/soap/encoding/'
    xmlns:xsi='http://www.w3.org/2001/XMLSchema-instance'
    xmlns:xsd='http://www.w3.org/2001/XMLSchema'
    xmlns:SOAP='http://schemas.xmlsoap.org/soap/envelope/'
    xmlns:SOAP-ENC="http://schemas.xmlsoap.org/soap/encoding/"  xmlns:dt='urn:schemas-microsoft-com:datat
  <SOAP:Body>
    <cli:echoStruct SOAP:encodingStyle='http://schemas.xmlsoap.org/soap/encoding/'
        xmlns:cli='http://soapinterop/' >
      <inputStruct>
        <varInt xsi:type="xsd:int" dt:dt="int">42</varInt>
        <varFloat xsi:type="xsd:float" dt:dt="float">99.004997</varFloat>
        <varString xsi:type="xsd:string" dt:dt="string">hello</varString>
      </inputStruct>
    </cli:echoStruct>
  </SOAP:Body>
</SOAP:Envelope>
```

Response message:

```
<?xml version="1.0" encoding="UTF-8" standalone="no"?>
<SOAP-ENV:Envelope
    xmlns:SOAPSDK1="http://www.w3.org/2001/XMLSchema"
    xmlns:SOAPSDK2="http://www.w3.org/2001/XMLSchema-instance"

SOAP Literal Encodings

15.8. XQuery 1.0 Support

The Virtuoso Server provides support for the XQuery 1.0 XML Query Language specification. This specification is currently in the working draft stage at the W3C XML Query Working Group working in collaboration with the W3C XSL Working Group. Both the syntax and semantics of XQuery will probably vary from version to version.

In addition to the XQuery 1.0 standard, which describes the language, the XQuery 1.0 and XPath 2.0 Functions and Operators Version 1.0 specification describes a set of built-in functions. As with all W3C in-progress efforts, there is a list of open issues detailing problems and unresolved areas; where these affect Virtuoso's implementation, they are noted below.

This chapter is not an XQuery textbook and does not replace XQuery-related specifications of W3C. Only Virtuoso-specific extensions and differences are described here.

The most important deviation from the standard is that Virtuoso does not provide full type information about data values. As a consequence, "typeswitch" and automatic type conversions are not implemented.

15.8.1. Types of XQuery Expressions

The current draft of XQuery lists 10 groups of XQuery expressions:

- Primary expressions, including literals, variable references and function calls.
- Path expressions, including all XPATH 1.0 expressions and a "pointer operator".
- Sequence expressions.
- Arithmetic, comparison and logical operators.
- Element constructors, which allow you to create new element nodes with specified names, lists of attributes and lists of children.
- FLWR (FOR-LET-WHERE-RETURN) expressions, which allow you to create variables for intermediate results and to transform sequences of items on a per-item basis.
- Ordered and unordered expressions to force some sorting of intermediate results or to prevent the XQuery processor from making redundant sorting.
- Control expressions, such as IF.
- Quantified expressions: SOME and EVERY.
- Expressions that test or modify data types.

Not all groups of expressions are implemented. In some groups, not all kinds of clauses are implemented.

In addition to the standard, Virtuoso supports special cases of FLWR expressions to deal with XML views:

- FOR Clause expressions with xmlview() function.

Primary Expressions

XQuery processor uses 32-bit integers on 32-bit platforms and 64-bit integers on 64-bit platforms. Similarly, the scale and precision of floating-point operations may vary from platform to platform.

Note that string literals are handled differently in XPath 1.0 and XQuery. "Ben "amp; Jerry"apos;s" denotes the string "Ben " Jerry's" in XQuery and the string "Ben "amp; Jerry"apos;s" in XPath.

Path Expressions

Any XPath 1.0 expression is a valid XQuery 1.0 path expression, which the Virtuoso XQuery processor supports. When invoked from the XQuery context, the XPath Processor works in accordance with XSLT rules. There are two major differences between standalone and XQuery/XSLT path expressions. First, the meaning of non-qualified name used as NameTest criterion, as described below. Second, the data type used for attributes varies. In XPath or XQuery mode, if a value is calculated by an

attribute:: axis, it is of type *attribute entity*; in standalone XPath, the string value of the attribute is used instead.

As specified in the XQuery 1.0 standard, a node-set returned by an XPath expression may be used as a sequence of items, where every node of that node-set becomes an item of the sequence. The opposite is not true, however. Not every sequence may be converted into a node-set, even if it is a sequence of nodes. If XPath starts from a function which returns a sequence, an error message "Context node is not an entity" is returned. Fortunately, a variable of type

```
sequence
```

may be used as a node-set if all items of the sequence are nodes.

Obsolete drafts of W3C specification contains description of "pointer operator". Virtuoso continues to support this operator to provide backward compatibility. XQuery processor needs DTD data associated with the XML document in question to distinguish ID attributes from other sorts of attributes and to bookmark elements that have ID locations. For more details, see the description of `id()` XPATH function. This function uses same DTD data for same purposes, so for any given document, either both `id()` and "pointer operator" are applicable or both does not work.

Sometimes the "Context node is not an entity" error is signalled if the beginning of the XPath expression is surrounded by parenthesis, even if the expression works fine without these parenthesis. This happens because "(...)" is an "append" operator in XQuery, not just a way to group subexpressions. "append" converts a node-set into a sequence even when it is called with a single argument - that is, without commas inside "(...)". This sequence cannot be used as input for the rest of the XPath expression.

As an syntax extension, special notation of QNames is added and can be used, e.g., in NameTest. An expanded name can be surrounded by delimiters (! and !), like (!http://www.example.com:MyTag!) and this syntax allows names that contain otherwise prohibited characters. This syntax is also useful when the text of the query is generated by software.

Note that the NameTest that consists of an unqualified name has different meanings in Virtuoso XPath and in XQuery. In XPath, NameTest "sample-tag" means "any element whose local-name is equal to sample-tag". In XQuery, the same test means "any element without namespace-uri whose local-name is equal to sample-tag".

Sequence Expressions

XQuery sequences are supported not only in XQuery but can also be handled in XPath and XSLT. When the XQuery processor is invoked from SQL and a sequence is returned to the caller, the sequence is automatically converted into a vector of its elements.

Virtuoso supports all sequence operations listed in current W3C paper plus deprecated operations BEFORE and AFTER.

The *sequence concatenation* operator is available in XPath and XSLT as the `append()` function. In addition, the `tuple()` function is available to get the first items of every given argument sequence and return the sequence of these items.

XQuery operators UNION, INTERSECT, EXCEPT are available in XPath and XSLT as functions `union()`, `intersect()` and `except()`.

Arithmetic, Comparison and Logical operations

Virtuoso shares the implementation of basic arithmetic and comparison operations between XPath, XQuery, XSLT, SQL and Virtuoso/PL processors, so type casting, scale and precision of calculated values are identical across the system. All operators are available in XQuery, in addition, << and >> operators are available in XPath and XSLT as `is_before()` and `is_after()` built-in functions.

Element Constructors

Virtuoso XQuery supports all XQuery 1.0 direct constructors. Previous versions of W3C draft contained the syntax for placing calculated content into the opening tag of direct element constructor, such as

```
<{concat("calculated-", "element-name")} {concat("calculated-", "attribute-name")}={concat("calculated-",
```

. Thus name of element or attribute, or a value of an attribute can be calculated dynamically. This syntax is still supported. The `create-element()` XPath function is implemented to make this functionality available in XPath. Additionally, a special function `create-attribute()` may be used to create a new dynamic attribute entity with value and name calculated, this works similarly to xsl:attribute XSLT instruction.

Similarly, `create-comment()`, `create-element()` and `create-pi()` mimics other XQuery direct constructors in XPath and XSLT.

The XQuery specification states that when sequence of atomic values is converted into content of an element constructor, whitespace character is inserted between adjacent values.

Unlike previous versions of Virtuoso, current XQuery syntax allows you to use "pure XML notation" inside element constructors. Thus there is no strict need to write 'constant' expression

```
<emp empid="12345"><name>John Smith</name><job>Bubble sorter</job></emp>
```

as it is dynamically calculated text, like

```
<emp empid="12345"><name>{'John Smith'}</name><job>{'Bubble sorter'}</job></emp>
```

It is still may be useful to write 'constant' expression in the old way. This artificial restriction simplifies finding syntax errors, because there are syntactically wrong expressions that are still correct "pure XML notation." Alternatively, CDATA sections also may be used to make it obvious that the string is a constant, not an expression with forgotten braces around it:

```
<emp empid="12345"><name><![CDATA[John Smith]]></name><job><![CDATA[Bubble sorter]]></job></emp>
```

The current version of Virtuoso does not support the new XQuery syntax for dynamic constructors.

FLWR Expressions

FLWR expressions are fully supported by Virtuoso XQuery. Moreover, `for()` and `let()` XPath functions are implemented to make this functionality available in XPath and XSLT. In addition, `assign()` and `progn()` functions are available to deal with extension functions, especially when extension functions are called for their side effects.

A special xmlview() function allows very efficient access to SQL data from XML views.

Previous XQuery specifications used "sort by" instead of "order by". The difference is that "sort by" was applicable to the final results of the FLWR statement made by RETURN clause whereas "order by" reorders input data for RETURN. Thus, "order by" can sort outputs using data that do not appear in the final result. E.g., an expression can collect items, "order" them by category and title but output only title and price. This was much harder in previous versions of XQuery because it was necessary to prepare an intermediate result that contained title and price and category, then do "sort" by category and title then use one more FLWR expression to form a result that is free from redundant data about category.

Nevertheless, Virtuoso supports both "sort by" and "order by", to keep backward compatibility. Moreover, "sort by" operator can be freely used with no relation to any FLWR subexpression. Typical use of such a simplified notation is

```
<hit-list>{//track[@rating] sort by (@rating descending)}</hit-list>
```

instead of portable

```
<hit-list>{for $t in //track[@rating] order by $t/@rating descending return $t}</hit-list>
```

Ordered and Unordered Expressions

The current version of Virtuoso does not use ordered/unordered hints. Everything is calculated ordered. This will change in the future but it is not advisable to place "unordered" hints for future use because there's no way to validate these hints. It is better to place appropriate comments but not hints.

Control Expressions

The `if()` special function mimics the XQuery operator for use in XPath and XSLT. Functions `and()` and `or()` are also control expressions because they calculate arguments in strict left-to-right order and may omit the calculation of some results.

Quantified Expressions

Both the *SOME* and *EVERY* operators are implemented. The `some()` and `every()` XPath functions are implemented to make this functionality available in XPath and XSLT.

Expressions That Test or Modify Data types

The operators *IS* , *CASTABLE* , *CAST* , *TREAT* , *TYPESWITCH* and *VALIDATE* are not implemented.

FOR Clause Expressions With xmlview() Function

XML views can be queried using FOR Clause from FLWR expressions. The `xmlview()` function allows XML views to be accessed as if they were XML documents. XPath expressions beginning with the `xmlview()` function will be translated into SQL statements to avoid redundant data access and to avoid creating a whole XML tree.

15.8.2. Details of XQuery Syntax

Virtuoso XQuery uses some syntax extensions. Most visible is an additional notation for qualified names as described above (name is surrounded by "(!...!)" delimiters. An earlier implementation allowed single-line comments started with "#" or "--" continuing to the end of line, this syntax is now obsolete.

The "default namespace declaration" clause is not currently supported, to make the text of XQuery unambiguous. If used, default namespaces must extend element names but not attribute names. Extension function names must be extended as they have non-default namespace prefixes but the names of basic functions should not be extended by the default namespace. Finally, Virtuoso will not preserve any information about used namespace prefixes, so default namespaces will be converted into non-default when the resulting XML entity is printed.

15.8.3. Pre-compilation of XPath and XQuery Expressions

Virtuoso compiles XPath and XQuery expressions as early as it is possible. E.g. if the first argument of `xquery_eval()` is a string constant then the SQL compiler will invoke the XQuery compiler to avoid on-demand compilation(s) of this text.

This feature significantly enhances performance of XQuery expressions embedded in SQL. For a simple search on XML document of average size the compilation time can be three times greater than execution time. In addition, the use of `sql:column()` special XQuery function is possible only when pre-compilation can be done by SQL compiler.

Pre-compilation is impossible if the text of the expression is not a constant. The typical case is passing an XQuery expression as parameter to a function. In this case the expression is compiled during the call of xquery_eval() and stored for future use. If the same string is passed again to the same invocation of xquery_eval() then a stored compiled expression is used.

Only partial pre-compilation is possible if XQuery expression refers to not-yet defined extension functions or to external resources. Partial pre-compilation gives little gain in speed, but it allows the use of `sql:column()`

The most important fact about pre-compilation is that passing parameters into XQuery statement is much more efficient than printing then into the text of the query. This is similar to SQL queries.

Example 15.22. Good and Poor Coding Practices

GOOD The expression is compiled once when SQL query is compiled:

```
select xquery_eval('count(//abstract)', SOURCE_XML) from LIB..ARTICLES;
```

GOOD The expression is compiled once when SQL query is compiled:

```
select xquery_eval('count(//article[@id=$main_id]/abstract)', SOURCE_XML, 1, vector('main_id', MAIN_ID))
  from LIB..ARTICLES;
```

POOR The expression is compiled once per data row. In addition, a hard-to-find error will occur if a value of MAIN_ID may contain double quote or a backslash character.

```
select xquery_eval(sprintf('count(//article[@id="%s"]/abstract)', MAIN_ID), SOURCE_XML)
  from LIB..ARTICLES;
```

GOOD The XQuery expression is compiled once per execution of the SQL query. The SQL compiler pays special attention to queries that import external resources, because the content and availability of these resources may differ from call to call. In addition, importing an external resource is usually not possible during SQL compilation due to deadlock danger, so the

compilation is postponed until run time, but this is not too bad anyway. Even in this sophisticated case, XQuery can contain calls of `sql:column()`.

```
select xquery_eval('
    namespace tools="http://www.example.com/lib/tools/"
    import define "http://www.example.com/lib/tools/common.xqr"
    tools:extract-keywords(//abstract)',
  SOURCE_XML)
from LIB..ARTICLES;
```

GOOD Two XQuery expressions are compiled during SQL compilation.

```
select
  case
    when SOURCE_IS_DOCBOOK then xquery_eval ('//formalpara[title="See Also"]/para', SOURCE_XML)
    else xquery_eval ('//p[@style="seealso"]', SOURCE_XML)
  end
from LIB..ARTICLES;
```

POOR Virtuoso can not pre-compile XQquery expressions. Moreover, only one precompiled expression is cached per occurrence of xquery_eval() in the SQL statement so it is possible that an XQuery compiler will start once per data row.

```
select
  xquery_eval (
    case
      when SOURCE_IS_DOCBOOK then '//formalpara[title="See Also"]/para'
      else '//p[@style="seealso"]'
    end,
  SOURCE_XML)
from LIB..ARTICLES;
```

15.9. XSLT Transformation

Virtuoso implements XSLT 1.0 transformations as SQL callable functions. In general, Virtuoso's XSLT processor follows the XSLT 1.0 standard as far as possible without loss of database-related functionality. The most important difference is in error handling. While XSLT rules assume that almost any error must be recovered, Virtuoso will stop the transformation in case of data access error or in case of serious arithmetic error, such as divide by zero. This is due to the greater complexity of the Virtuoso XSLT processor's environment. Standalone processors generally accept a set of files as input parameters, the only output is the resulting transformation as a file, and all configuration parameters are listed on the command line. Virtuoso's XSLT processor may retrieve both data and stylesheets from local filesystems, local tables, remote datasources, or the Web. Parameters of the stylesheet transformation may be prepared by complicated Virtuoso PL procedures and so on. Plain XSLT processors may continue producing "dirty" output; Virtuoso's processor will stop upon encountering serious in order to produce helpful error diagnostics.

Another important difference is that Virtuoso has one processor for XSLT, XPath and XQuery. The user will find this convenient because an application may use XSLT-specific functions in XPath expressions, XQuery functions in XSLT, and so on. If extension functions are defined for the XSLT processor, they may also be used in XPath and XQuery expressions without any additional operations. One caveat is that this may invalidate some rules related to the document order of nodes in node-sets. Both the XPath 1.0 and XSLT 1.0 standards say that some functions must process the node that is first in document order from a given node-set. In such cases Virtuoso's processor will process the first node found in the node-set, regardless of whether it is actually the first in document order or not. This is done because the old XPath rule is nonsensical if nodes of the node-set are retrieved from more than one document or are created in the query. The processor follows the old rule for 99% of real expressions. Specifically, it fully matches the standards' rules for all XPath expressions that are free of reverse-order axes and non-standard functions.

15.9.1. Namespaces

In the following the

```
xsl:
```

namespace prefix is used to mean "http://www.w3.org/XSL/Transform/1.0". In fact all namespace URI's beginning with "http://www.w3.org/XSL/Transform" are considered as the XSLT namespace. The namespaces

"http://www.w3.org/1999/XSL/Transform" and "http://www.w3.org/TR/WD-xsl" are recognized as synonymous. No other namespace URI's have special significance.

15.9.2. The *<xsl:output>* Tag

The Virtuoso XSLT processor recognizes and verifies the *<xsl:output>* tag. The only *<xsl:output>* attributes that are used are the *method*, *encoding*, *omit-xml-declaration*, *media-type*, *doctype-public* *doctype-system* and *indent*. The processor output is created in the character set that is in effect for the client or the one specified by encoding.

The SQL function `xml_tree_doc_media_type()` returns the media type in effect for the result of the `xslt()` function based on the xsl:output *media-type* and *method* attributes of the stylesheet applied. This method is also used for producing FOR XML AUTO WebDAV resources for HTTP reply generation.

15.9.3. External Parameters in XSLT Stylesheets

The XSLT 1.0 standard specifies that parameters may be passed to the XSLT processor from its environment in order to control data transformation, but the details are implementation-specific. Virtuoso's XSLT Processor will accept default values for global parameters from the optional third argument of the xslt() Virtuoso PL function. This argument, if specified, must be a vector of parameter names and values of the form

```
vector(name1, value1,... nameN,
valueN)
```

, where *name1 ... nameN* must be of type *varchar*, and *value1 ... valueN* may be of any Virtuoso datatype, but may not be null. If a parameter has a null value specified, it is removed from the vector without any further processing. After removal of null values, duplicate names are eliminated. If a name occurs more than once in the vector, only the last one will be retained.

When the XSLT Processor begins the transformation of the document, it creates two stacks of variables, one for global variables and one for local variables. Initially the stacks are empty. Then it prepares temporary indexes for all *<xsl:key>* elements; all future calls of `key()` function will return without any searches through the source document. Only after the processing of all keys of the stylesheet, the XSLT Processor pushes all parameters from the third argument of the `xslt()` function into the stack of local variables. Then, as described in the XSLT specification, it initializes top-level variables and parameters. For every *<xsl:variable>* or *<xsl:param>* element found at the top-level of the main stylesheet or at the top level of some imported stylesheet, the processor calculates the value and pushes the created variable into the stack of local variables. The *<xsl:param>* element is ignored if the specified name is already declared in the vector of parameters or in some stylesheet imported before. When all top-level variables and parameters are initialized, the content of the stack of local variables is moved into the stack of global variables, and the stack of local variables is made empty. During the rest of the XSLT transformation, these variables will be used as global variables. They may be temporarily shadowed by inner declarations of local variables - though not by declarations of local parameters - but they cannot be changed. Note that expressions for values of variables and parameters may contain calls of `key()` function, because temporary indexes are ready to use before the first such expression is calculated. Expressions of *<xsl:key>* elements may not refer to any parameters or variables, due to the same reason.

15.9.4. Functions

The `xslt()` Virtuoso/PL function applies a given stylesheet to a given source XML document and returns the transformed document. There is no restriction to what a VSP page can output, this is usually HTML but can be XML. The function `http_xslt()` allows a stylesheet to be applied to a whole output of an VSP page before it is sent to the user agent. Functions `xslt_sheet()` and `xslt_stale()` allow you to create and destroy a stylesheet dynamically. Function `xmlupdate()` is convenient for very simple "search-and replace" transformations.

15.9.5. XSLT Examples

This section covers some examples of applying XSLT to various stored data.

Example 15.23. XSLT example

```
create procedure xml_view_string (in _view varchar)
{
  declare _body any;
  declare _pf varchar;
  _body := string_output ();
```

```
  http ('<document>', _body);
  _pf := concat ('DB.DBA.http_view_', _view);
  call (_pf) (_body);
  http ('</document>', _body);

  return (string_output_string (_body));
}

create procedure xslt_view (in v varchar, in xst varchar)
{

  declare str, r varchar;
  xslt_sheet (xst, xtree_doc (file_to_string (xst)));
  str := xml_view_string (v);
  r := xslt (xst, xtree_doc (str));
  declare str_out any;
  str_out := string_output ();
  http_value (r, 0, str_out);
  string_to_file ('xslt.out', string_output_string (str_out), 0);
}
```

These functions will take the serialized text of an XML view created with CREATE XML VIEW, transform it with a stylesheet and store the result into a file.

The first function returns a string containing the text generated as the value of the XML view specified as argument. It calls the serialization function, which is

```
DB.DBA.http_view_ +
view name
```

. This function writes the text into the string output stream passed to it. Note that the function wraps the text inside a *<document>* element in order to make it well-formed, since the view serialization function will emit multiple top-level elements, one for each selected row in the root table in the XML view.

The `xslt_view()` function first defines the style sheet, which it takes from a file in this case. The `xslt_sheet()` function is called with the name and root element of the parsed file.

The function next gets the string to process, parses it as XML, and converts the parse tree into an entity object. This is then passed to the `xslt()` function. The result is another entity object. This is finally serialized as XML text and written into the file *xslt.out*.

These examples show how to parse and serialize XML using varchars, string output streams and the entity data type.

The central points are:

1. The XML entity object is a reference to a particular element of a parsed XML document, The underlying document is only visible through this reference. A string is converted into such a document and a reference to the document's root is returned by the

   ```
   xtree_doc (string)
   ```

   function. In previous versions of Virtuoso, the combination

   ```
   xml_tree_doc (xml_tree (string))
   ```

   was used for this purpose; this combination still works to maintain backwards compatibility, but using xtree_doc() is preferable.
2. A string output is used to capture the serialization of data by the `http_value()` function. If the string output were not specified the data would be sent to the HTTP client directly, if we were running in an HTTP request context.

15.9.6. XPath Function Extensions for XSLT

Virtuoso provides a way to extend the abilities of the XSLT processor by creating user defined XPath functions. The functions `xpf_extension()` and `xpf_extension_remove()` allow addition and removal of XPath extension functions.

15.9.7. Status Of XSLT And XPath Implementation

Items marked with (*) are currently not implemented.

15.10. XMLType

XMLType is a predefined type for representing XML entities as UDT objects. This is compatible with Oracle9i and later. You can get better performance and flexibility by using use plain built-in functions that directly operate with XML entities. All predefined member functions of XMLType for extracting fragments from an XMLType are actually wrappers for `xpath_eval()` built-in function. You can declare a column of XMLType but the actual type of the created column will be "LONG XML". Thus any XML-related feature that can be used for "LONG XML" column will work with XMLType. E.g. WITH SCHEMA constraint allows you to force stored values to match a particular schema; XML free text index can accelerate search for documents by content etc.

XMLType behaves like any user-defined type, with the only difference in type conversion rules. If an XML entity is passed as an argument instead of an instance of XMLType, a new instance of XMLType is created by a constructor that takes the entity as an argument. Similarly, functions that accept XML entities as arguments can also accept an instance of XMLType as an actual value of argument.

The following example creates a table with an XMLType column, put two records there and performs a simple search:

```
CREATE TABLE Xml_tab ( xmlval XMLType);

INSERT INTO Xml_tab VALUES (
   xmltype('<?xml version="1.0"?>
               <EMP>
                  <EMPNO>221</EMPNO>
                  <ENAME>John</ENAME>
               </EMP>'));

INSERT INTO Xml_tab VALUES (
   xmltype('<?xml version="1.0"?>
               <PO>
                  <PONO>331</PONO>
                  <PONAME>PO_1</PONAME>
               </PO>'));

-- now extract the numerical values for the employee numbers

SELECT e.xmlval.extract('//EMPNO/text()').getNumVal() as empno
   FROM Xml_tab
   WHERE e.xmlval.existsnode('/EMP/EMPNO')  = 1;
```

To create a new instance of XMLType, the constructor `XMLType()` or a function `createXML()` is used.

Virtuoso can perform XPATH search in XMLType instances: `extract()` and `existsNode()` member functions are convenient for simple searches and any built-in XPATH functions like `xpath_eval()` or `xquery_eval()` can handle

XMLType parameters instead of XML entity parameters. An application can use `getStringVal()` , `getNumVal()` and `getColbVal()` member functions to convert found node to strings, numbers or an XML source text of the node.

Instances of the type can store the URL of the XML schema to which they should conform. This URL can be specified when an instance is constructed; Once an instance is created, its schema URL cannot be changed but a modified copy can be created by `createSchemaBasedXML()` and `createNonSchemaBasedXML()` member functions; `isSchemaBased()` and `getSchemaURL()` member functions check whether the given instance is schema based or not and what particular schema is used.

An schema based XMLType instance can be validated against its schema; If it has been validated against its schema once with no errors detected then a special "VALIDATED" flag is set in the instance indicating that there is no need to validate it again. `schemaValidate()` member function performs the validation, `isSchemaValidated()` queries the "VALIDATED" flag and `setSchemaValidated()` changes the "VALIDATED" flag if application needs optimization tricks.

In addition, any instance can be validated against an arbitrary schema via member function `isSchemaValid()` . Built-in function `xml_validate_schema()` may accept instance of XMLType as its first argument, providing even more validation functionality.

15.11. Changing XML entities in DOM style

An application may need to perform small irregular changes in an XML document. It can be time-consuming to create a modified copy of a whole document for making each small change. It can be also hard to express condition for making the change in terms of XPath in order to use XSLT or XQuery.

Virtuoso offers a way to modify an existing XML entity by local operations like "insert a subtree before current node" or "replace one subtree with a given one". These operations are called DOM operations because they are similar to JavaScript operations with the Document Object Model.

DOM operations are the only operations that change an existing XML document instead of creating a new modified document. It is very important to understand that one document can be shared between many XML entities so changes made via one entity may affect data accessible via other entities that share the same document. Every XML document has special flags to "lock" its content and thus prevent the content from being changed. E.g. XSLT and XQuery processors optimize access to the source document in hope that every access to any entity will produce the same result during the whole run of the processor. If an extension function will modify the source document in the middle then the result of the processing is probably corrupted and this error may be very hard to detect and debug. To prevent this sort of problems, the XSLT processor locks the source at start and unlock at end so any attempt to modify the source during the run will signal an error. The document can be locked in the following cases:

- The document is the source of the XSLT processing that is in progress.
- The document contains the context node that is passed to the XQuery processor at start.
- The document is used as a external generic entity in some other document.
- The document is created by the call of XPath function doc, document or document-literal during the processing of some other document and that document is still in use.

One additional issue of using DOM operations is that any DOM operation invalidates DTD and schema validation information that was associated with the document before the operation.

- **Schema validation status ("is validated" flag).** E.g. if an schema based instance of XMLType is validated against its schema and thus it has set its "is validated" flag to 1 then the flag is to be reset to zero if the XML entity of this instance is modified by DOM operation, because there is no guarantee that the modified document is still valid against the declared schema; if the application will repeat the validation and it is successful then the flag will be set to 1 again.
- **DTD-based processing of ID attributes.** A validating XML parser can build special dictionaries of ID attributes when it reads a document. These dictionaries are used by `id` XPATH function and "pointer operator" of XQuery to find a node labeled by a given ID value without searching the whole document. Any change in document tree invalidates data in these dictionaries so any access to them will signal an error.

15.11.1. Composing Document Fragments From DOM Function Arguments

When a DOM modification function adds some nodes to the tree, the content of these nodes comes from values of arguments of the function. In the most common case, some generic entity is created from one or more arguments and the function adds the content of the entity into the appropriate place of the document. This process is regulated by a small set of very intuitive rules.

All data to be inserted are calculated before any modification of the document is started. For example it is safe to insert into the document a fragment of this document, even if it contains the point of insertion; such operation will never cause infinite loops.

If an instance of XMLType is passed then its internal XML entity is used.

If an argument is neither an XML entity nor a string then it is cast to the string first.

If an argument is NULL then it is fully ignored, as if there is no such argument at all.

A root node of a document can not be added into the tree of other document. Instead, every child node of the root (i.e. every top-level node of the document) is added to the target document, the order of child nodes will be preserved. An XML document usually contains only one top-level element node, but it also can contain comment and processing instruction nodes at top-level. Depending on the application, such comments and instructions may be inappropriate in the middle of the modified document. Thus it is worth to check what the application should insert: the root node with everything inside or only a top-level element node.

If some function accepts a list of arguments as list of values to be inserted, these values will be concatenated into a single generic entity. It is important to remember that the XML document can not contain two neighbour text nodes. If two consecutive arguments are strings then a single node that is a concatenation of these string is added. If the value of one argument is a string and the value of the next argument is a tree fragment that starts with a string then this pair of strings will also be replaced with a concatenation of these strings. When a function inserts a text after some existing text node of the XML document, no new node is created and the existing text node is replaced with the text node that is the concatenation of old and new texts.

In general, you should not expect that adding N values into the document will add N new nodes to the document. It can add a lesser number of nodes due to ignoring NULLs and concatenating some texts. It can also add a greater number of nodes if some values are root nodes with many children.

Chapter 16. RDF Data Access and Data Management

Abstract

Starting with version 4.5, Virtuoso provides built-in support for SPARQL, the standard query language for RDF and the semantic web. Adoption of SPARQL with Virtuoso is effortless, as any existing SQL client applications and stored procedures can take advantage of SPARQL simply by using it in the place of or inside SQL queries. Additionally, Virtuoso offers the standard SPARQL protocol to HTTP clients. From version 5.0.7, Virtuoso can be used as the RDF store/query processor of the Jena and Sesame RDF frameworks.

This chapter discusses Virtuoso's RDF triple storage and query capabilities. This discusses storing RDF data as well as mapping existing relational data into RDF for SPARQL access. Numerous SPARQL language extensions and standard compliance are covered.

In this chapter SPARQL and SPASQL are used as siblings.

- Geometry Data Types and Spatial Index Support

16.1. Data Representation

This section covers how Virtuoso stores RDF triples. The IRI_ID built-in data type is introduced, along with the default table structures used for triple persistency. These details are mostly hidden from users of RDF, thus this section is not necessary reading for typical use of Virtuoso with RDF.

16.1.1. IRI_ID Type

The central notion of RDF is the IRI, or URI, which serves as the globally unique label of named nodes. The subject and predicate of a triple are always IRI's and the object may be an IRI or any other XML Schema scalar data type. In any case, an IRI is always distinct from any instance of any other data type.

Virtuoso supports a native IRI_ID data type, internally an unsigned 32 bit or unsigned 64 bit integer value. Small databases can use 32 bit values but if database becomes big then the administrator should execute `DB.DBA.RDF_64BIT_UPGRADE ()` procedure that will switch to 64-bit values. This procedure takes time so if it is known in advance that the database will grow to billions of nodes then it could be convenient to upgrade it while it is empty. An IRI_ID is never equal to any instance of any other type.

Thus, the object column of a table storing triples can be declared as ANY and IRI values will be distinguishable without recourse to any extra flag and IRI's will naturally occupy their own contiguous segment in the ANY type collation sequence. Indices can be defined over such columns. An IRI_ID is never automatically cast into any other type nor any other type into IRI_ID.

The functions iri_id_num (in i IRI_ID) and iri_id_from_num (in n INT) convert between signed integers and IRI_ID's. The function isiri_id (in i any) returns nonzero if the argument is of type IRI_ID, zero otherwise.

The syntax for an IRI_ID literal is *#i<NNN>* or *#ib<NNN>* , where *<NNN>* is up to 20 decimal digits. *#i12345* is equal to *iri_id_from_num (12345)* and *#ib12345* is equal to *iri_id_from_num (12345) + min_64bit_bnode_iri_id ()* .

When received by a SQL client application, the ODBC driver or interactive SQL will bind an IRI_ID to a character buffer, producing the *#i<NNN>* syntax. When passing IRI_ID's from a client, one can pass an integer and use the iri_id_from_num () function in the statement to convert server side. A SQL client will normally not be exposed to IRI_ID's since the SPARQL implementation returns IRI's in their text form, not as internal id's. These will however be seen if reading the internal tables directly.

Note

Nobody, even DBA, should write directly to internal RDF tables, because some data from that tables are cached in a special way and cache is not automatically updated when content of tables has changed.

Example

The following example demonstrates IRI type usage as Virtuoso PL function parameter:

```
SQL>create procedure vs_property_label (in _uri varchar)
  {
    declare res varchar;
    result_names (res);
    for (sparql define input:storage "" select distinct ?graph_rvr_fixed where { graph `iri(?:_uri)` { ?q
    do {
```

```
      result ("graph_rvr_fixed");
    }
  }
;
Done. -- 0 msec.

SQL>select vs_property_label('http://www.openlinksw.com/schemas/virtrdf#');
res
VARCHAR

16.1.2. RDF_BOX Type

While strings, numbers, dates and XML entities are "native" SQL datatypes, RDF literal with non-default type or language have no exact matches among standard SQL types. Virtuoso introduces a special data type called "RDF_BOX" in order to handle that cases. Instance of RDF_BOX consists of data type, language, the content (or beginning characters of a long content) and a possible reference to DB.DBA.RDF_OBJ table if the object is too long to be held in-line in some table or should be outlined for free-text indexing.

Usually applications do not need to access internals of an RDF boxes. This datatype is used in system tables but almost all SPARQL and RDF operations use standard SQL datatypes for arguments and return values.

16.1.3. RDF_QUAD and other tables

The main tables of the default RDF storage system are:

```
create table DB.DBA.RDF_QUAD (
  G IRI_ID,
  S IRI_ID,
  P IRI_ID,
  O any,
  primary key (G,S,P,O) );
create bitmap index RDF_QUAD_OGPS on DB.DBA.RDF_QUAD (O, G, P, S);
```

Each triple (more correctly, each quad) is represented by one row in RDF_QUAD. The columns represent the graph, subject, predicate and object. The IRI_ID type columns reference RDF_IRI, which translates the internal id to the external name of the IRI. The O column is of type ANY. If the O value is a non-string SQL scalar, such as a number or date or IRI, it is stored in its native binary representation. If it is a "very short" string (20 characters or less), it is also stored "as is". Long strings and RDF literal with non-default type or language are stored as RDF_BOX values. Instance of rdf_box consists of data type, language, the content (or beginning characters of a long content) and a possible reference to RDF_OBJ if the object is too long to be held in-line in this table or should be outlined for free-text indexing.

```
create table DB.DBA.RDF_PREFIX (
```

```
  RP_NAME varchar primary key,
  RP_ID int not null unique );
create table DB.DBA.RDF_IRI (
  RI_NAME varchar primary key,
  RI_ID IRI_ID not null unique );
```

These two tables store a mapping between internal IRI id's and their external string form. A memory-resident cache contains recently used IRIs to reduce access to this table. Function id_to_iri (in id IRI_ID) returns the IRI by its ID. Function iri_to_id (in iri varchar, in may_create_new_id) returns an IRI_ID for given string; if the string is not used before as an IRI then either NULL is returned or a new ID is allocated, depending on the second argument.

```
create table DB.DBA.RDF_OBJ (
  RO_ID integer primary key,
  RO_VAL varchar,
  RO_LONG long varchar,
  RO_DIGEST any
)
create index RO_VAL on DB.DBA.RDF_OBJ (RO_VAL)
create index RO_DIGEST on DB.DBA.RDF_OBJ (RO_DIGEST)
;
```

When an O value of RDF_QUAD is longer than a certain limit or should be free-text indexed, the value is stored in this table. Depending on the length of the value, it goes into the varchar or the long varchar column. The RO_ID is contained in rdf_box object that is stored in the O column. Still, the truncated value of O can be used for determining equality and range matching, even if < and > of closely matching values need to look at the real string in RDF_OBJ. When RO_LONG is used to store very long value, RO_VAL contains a simple checksum of the value, to accelerate search for identical values when the table is populated by new values.

```
create table DB.DBA.RDF_DATATYPE (
    RDT_IID IRI_ID not null primary key,
    RDT_TWOBYTE integer not null unique,
    RDT_QNAME varchar );
```

The XML Schema data type of a typed string O represented as 2 bytes in the O varchar value. This table maps this into the broader IRI space where the type URI is given an IRI number.

```
create table DB.DBA.RDF_LANGUAGE (
    RL_ID varchar not null primary key,
    RL_TWOBYTE integer not null unique );
```

The varchar representation of a O which is a string with language has a two byte field for language. This table maps the short integer language id to the real language name such as 'en', 'en-US' or 'x-any'.

Note that unlike datatype names, language names are not URIs.

A short integer value can be used in both RDF_DATATYPE and RDF_LANGUAGE tables for two different purposes. E.g. an integer 257 is for 'unspecified datatype' as well as for 'unspecified language'.

16.1.4. Short, Long and SQL Values

When processing an O, the SPARQL implementation may have it in one of three internal formats, called "valmodes". The below cases apply for strings:

The short format is the format where an O is stored in RDF_QUAD.

The long value is similar to short one but an rdf_box object, that consists of six fields:

- short integer id of type referencing RDT_TWOBYTE, 257 if the type is not specified,
- the string as inlined in O or as stored in RO_VAL or RO_LONG,
- the RO_ID if the string is from RDF_OBJ (otherwise zero),
- the short integer id of language referencing RL_TWOBYTE, 257 if the language is not specified,
- flag whether the stored string value is complete or it is only the beginning that is inlined in O.

The SQL value is the string as a narrow string representing the UTF8 encoding of the value, stripped of data type and language tag.

The SQL form of an IRI is the string. The long and short forms are the IRI_ID referencing RU_IRI_ID of RDF_URL.

For all non-string, non-IRI types, the short, long and SQL values are the same SQL scalar of the appropriate native SQL type. A SQL host variable meant to receive an O should be of the ANY type.

The SPARQL implementation will usually translate results to the SQL format before returning them. Internally, it uses the shortest possible form suited to the operation. For equalities and joining, the short form is always good. For range comparisons, the long form is needed etc. For arithmetic, all three forms will do since the arguments are expected to be numbers which are stored as their binary selves in O, thus the O column unaltered and uncast will do as an argument of arithmetic or numeric comparison with, say, SQL literal constants.

16.1.5. Programatically resolving DB.DBA.RDF_QUAD.O to SQL

This section describes how to resolve programatically the internal representation of DB.DBA.RDF_QUAD.O to its SQL value.

When operating over RDF_QUAD table directly, in order to transform all values obtained from column O to the explicit SQL type in a programmatic way, should be used the following hints depending on the case:

- The SQL value can be extracted as

  __ro2sq(O)

  .
- The datatype can be extracted as

  DB.DBA.RDF_DATATYPE_OF_OBJ (O)

  if IRI_ID of the type is enough or

  __ro2sq (DB.DBA.RDF_DATATYPE_OF_OBJ(O))
- The language can be extracted as

  DB.DBA.RDF_LANGUAGE_OF_OBJ (O)

  .

It could be helpful to be created an Linked Data View for a custom table with formats rdfdf:default or rdfdf:default-nullable for columns similar to O, and let SPARQL perform the rest.

To track SPARQL, use the following functions:

```
select sparql_to_sql_text ('query text here without a leading SPARQL keyword and trailing semicolon')
```

or

```
string_to_file ('filename.sql', sparql_to_sql_text ('query text'), -2);
```

So for example to track the following SPARQL query:

```
SPARQL define input:storage ""
select distinct ?graph_rvr_fixed
from <http://www.openlinksw.com/schemas/virtrdf#>
where { ?qmv virtrdf:qmGraphRange-rvrFixedValue ?graph_rvr_fixed }
```

execute

```
SQL>select sparql_to_sql_text('define input:storage "" select distinct ?graph_rvr_fixed from <http://www.
callret
VARCHAR
_______________________________________________________________________________
```

```
 SELECT  __ro2sq ("s-1-0_rbc"."graph_rvr_fixed") AS "graph_rvr_fixed" FROM (SELECT DISTINCT __rdf_sqlval_
rvr_fixed */ /*]retval*/ ) AS /*tmpl*/ "graph_rvr_fixed"
    FROM DB.DBA.RDF_QUAD AS "s-1-1-t0"
    WHERE /* field equal to URI ref */
        "s-1-1-t0"."G" = __i2idn ( /* UNAME as sqlval */ __box_flags_tweak ( 'http://www.openlinksw.com/s
        AND  /* field equal to URI ref */
        "s-1-1-t0"."P" = __i2idn ( /* UNAME as sqlval */ __box_flags_tweak ( 'http://www.openlinksw.com/s
1))
OPTION (QUIETCAST)) AS "s-1-0_rbc"

1 Rows. -- 321 msec.
```

or

```
SQL>string_to_file ('mytest.sql', sparql_to_sql_text ('define input:storage "" select distinct ?graph_rvr
```

As result will be created file with the given name, i.e. mytest.sql and its content should be:

```
 SELECT  __ro2sq ("s-1-0_rbc"."graph_rvr_fixed") AS "graph_rvr_fixed" FROM (SELECT DISTINCT __rdf_sqlval_
    FROM DB.DBA.RDF_QUAD AS "s-1-1-t0"
    WHERE /* field equal to URI ref */
        "s-1-1-t0"."G" = __i2idn ( /* UNAME as sqlval */ __box_flags_tweak ( 'http://www.openlinksw.com/s
        AND  /* field equal to URI ref */
        "s-1-1-t0"."P" = __i2idn ( /* UNAME as sqlval */ __box_flags_tweak ( 'http://www.openlinksw.com/s
OPTION (QUIETCAST)) AS "s-1-0_rbc"
```

16.1.6. Special Cases and XML Schema Compatibility

We note that since we store numbers as the equivalent SQL binary type, we do not preserve the distinction of byte, boolean etc. These all become integer. If preserving such detail is for some reason important, then storage as a typed string is possible but is not done at present for reasons of compactness and performance.

16.1.7. SQL Compiler Support - QUIETCAST option

The type cast behaviors of SQL and SPARQL are different. SQL will generally signal an error when an automatic cast fails. For example, a string can be compared to a date column if the string can be parsed as a date but otherwise the comparison should signal an error. In SPARQL, such situations are supposed to silently fail. Generally, SPARQL is much more relaxed with respect to data types.

These differences will be specially noticed if actual SQL data is processed with SPARQL via some sort of schema mapping translating references to triples into native tables and columns.

Also, even when dealing with the triple-oriented RDF_QUAD table, there are cases of joining between S and O such that the O can be a heterogeneous set of IRI's and other data whereas the S is always an IRI. The non-IRI to IRI comparison should not give cast errors but should silently fail. Also, in order to keep queries simple and easily optimizable, it should not be necessary to introduce extra predicates for testing if the O is n IRI before comparing with the S.

Due to these considerations, Virtuoso introduces a SQL statement option called QUIETCAST. When given in the OPTION clause of a SELECT, it switches to silent fail mode for automatic type casting.

The syntax is as follows:

```
SELECT ...
FROM .... OPTION (QUIETCAST)
```

This option is automatically added by the SPARQL to SQL translator. The scope is the enclosing procedure body.

16.1.8. Dynamic Renaming of Local IRI's

There are cases where it is desirable to have IRI's in RDF storage that will change to reflect a change of the host name of the containing store. This is specifically true of DAV resource metadata for local DAV resources. Such IRI's must be stored prefixed with `local:`.

If a user application makes statements with such a URI, then these statements will be returned with local: substituted with a prefix taken from the context as described below.

When returning IRI's from id's, this prefix is replaced by the Host header of the HTTP request and if not running with HTTP, with the DefaultHost from URIQA. This behavior is always in effect.

When converting strings to IRI id's, the `local:` prefix may or may not be introduced depending on ini file and other context factors. If DynamicLocal defined in the [URIQA] section of the Virtuoso INI file is on and the host part of the IRI matches the Host header of the HTTP request in context or the DefaultHost if outside of HTTP context, then this is replaced with local: before looking up the IRI ID. Even if DynamicLocal is not on and the `local:` prefix occurs in the IRI string being translated to id, the translating the IRI_ID back to the IRI name will depend on the context as described above.

The effects of DynamicLocal = 1 can be very confusing since many names can refer to the exact same thing. For example, if the DefaultHost is dbpedia.org, `iri_to_id ('http://dbpedia.org/resource/Paris') = iri_to_id ('local:///resource/Paris)` is true and so is `'http://dbpedia.org/resource/Paris' = id_to_iri (iri_to_id ('local://resource/Paris'))` These hold in a SQL client context, i.e. also when connected through RDF frameworks like Jena or Sesame. When running a SPARQL protocol request, the Host: header influences the behavior, likewise when using web interactive SQL in Conductor. Also be careful when loading RDF files that may have URI's corresponding to the local host name.

16.2. SPARQL

16.2.1. SPARQL Implementation Details

Virtuoso's RDF support includes in-built support for the SPARQL query language. It also includes a number of powerful extensions that cover path traversal and business intelligence features. In addition, there is in-built security based on Virtuoso's support for row level policy-based security, custom authentication, and named graphs.

The current implementation does not support some SPARQL features:

- Unicode characters in names are not supported.
- Comments inside SPARQL queries are not supported when the query is inlined in SQL code.

On the other hand, Virtuoso implements some extensions to SPARQL:

- SPARUL statements, such as

  insert , *modify* , *load* etc, are supported.
- The SPARQL compiler can be configured using

  define ...

  clauses, e.g.

  define output:valmode "LONG"

  .
- Expressions are allowed in triple patterns, both in a

  where

  clause and in constructor patterns. Such expressions are delimited by backquotes.
- Expressions are allowed in select statement result lists.
- Parameters can be passed to the query from outside, using

  ?:variablename

  syntax.
- Aggregate functions are supported.
- Subqueries may appear where group patterns are allowed.

- A set of operators has been added to configure the mapping of relational data to RDF (aka Linked Data Views).

The following listing shows the SPARQL grammar expressed in BNF, including all Virtuoso extensions but excluding rules for the syntax of each lexical element. Rule numbers in square brackets are from W3C normative SPARQL grammar. An asterisk indicates that the rule differs from the W3C grammar due to Virtuoso extensions - *[Virt]* means that the rule is Virtuoso-specific, *[DML]* indicates a data manipulation language extension from SPARUL.

[Virt]  QmSqlId          ::=  PLAIN_ID | 'TEXT' | 'XML'
[Virt]  QmIRIrefConst    ::=  IRIref | ( 'IRI' '(' String ')' )
```

Example: Using OFFSET and LIMIT

Virtuoso uses a zero-based index for OFFSET. Thus, in the example below, the query returns 1000 rows starting from, and including, record 9001 of the result set. Note that the default value of the MaxSortedTopRows parameter in the [Parameters] section of the virtuoso.ini configuration file defaults to 10000, so in this example its value will need to have been increased beforehand.

```
SQL>SELECT ?name
ORDER BY ?name
OFFSET 9000
LIMIT 1000
```

LIMIT applies to the solution resulting from the graph patterns specified in the WHERE CLAUSE. This implies that SELECT and CONSTRUCT/DESCRIBE queries will behave a little differently. In the case of a SELECT, there is a straight translation i.e. LIMIT 4 implies 4 records in the result set. In the case of CONSTRUCTs where the solution is a graph (implying that the existence of duplicates and/or unbound variables is common) LIMIT is basically a maximum triples threshold of: [Solution Triples] x [LIMIT].

Example query:

```
SQL>SPARQL
prefix dct:<http://purl.org/dc/terms/>
prefix rdfs:<http://www.w3.org/2000/01/rdf-schema#>

CONSTRUCT { ?resource dct:title ?title ;
                      a ?type }

FROM <http://msone.computas.no/graphs/inferred/classification>
FROM <http://msone.computas.no/graphs>
FROM <http://msone.computas.no/graphs/instance/nfi>
FROM <http://msone.computas.no/graphs/instance/mo>
FROM <http://msone.computas.no/graphs/ontology/mediasone>
FROM <http://msone.computas.no/graphs/vocab/mediasone>
FROM <http://msone.computas.no/graphs/inferred/nfi/realisation1>
FROM <http://msone.computas.no/graphs/inferred/mo/realisation1>
FROM <http://msone.computas.no/graphs/inferred/nfi/realisation2>
FROM <http://msone.computas.no/graphs/inferred/mo/realisation2>
FROM <http://msone.computas.no/graphs/inferred/agent-classification>
FROM <http://msone.computas.no/graphs/ontology/mediasone/agent>

WHERE {
  {
?resource a ?type .
  FILTER (?type = <http://www.w3.org/2002/07/owl#Class> ) .
  ?resource rdfs:label ?title .
  } UNION {
?resource a ?type .
  FILTER (?type in (
          <http://musicbrainz.org/mm/mm-2.1#Track> ,
          <http://www.csd.abdn.ac.uk/~ggrimnes/dev/imdb/IMDB#Movie> ,
          <http://xmlns.com/foaf/0.1/Image> ,
          <http://www.computas.com/mediasone#Text> ) ) .
  ?resource dct:title ?title .
  }
  FILTER regex(?title, "turi", "i")
}
ORDER BY ?title LIMIT 4 OFFSET 0
```

Example: Prevent Limits of Sorted LIMIT/OFFSET query

The DBpedia SPARQL endpoint is configured with the following INI setting:

```
MaxSortedTopRows = 40000
```

The setting above sets a threshold for sorted rows. Thus, when using basic SPARQL queries that include OFFSET and LIMIT the following query will still exist the hard limit set in the INI:

```
DEFINE sql:big-data-const 0
SELECT DISTINCT  ?p ?s
FROM <http://dbpedia.org>
WHERE
  {
    ?s ?p <http://dbpedia.org/resource/Germany>
  }
ORDER BY ASC(?p)
OFFSET  40000
LIMIT   1000
```

returns the following error on execution:

```
HttpException: 500 SPARQL Request Failed
```

```
Virtuoso 22023 Error SR353: Sorted TOP clause specifies more then 41000 rows to sort.
Only 40000 are allowed.
Either decrease the offset and/or row count or use a scrollable cursor
```

To prevent the problem outlined above you can leverage the use of subqueries which make better use of temporary storage associated with this kind of quest. An example would take the form:

```
SELECT ?p ?s
WHERE
  {
    {
      SELECT DISTINCT ?p ?s
      FROM <http://dbpedia.org>
      WHERE
        {
          ?s ?p <http://dbpedia.org/resource/Germany>
        } ORDER BY ASC(?p)
    }
  }
OFFSET 50000
LIMIT 1000
```

SPARQL and XQuery Core Function Library

In the current implementation, the XQuery Core Function Library is not available from SPARQL.

As a temporary workaround, string parsing functions are made available, because they are widely used in W3C DAWG examples and the like. They are:

```
xsd:boolean (in strg any) returns integer
xsd:dateTime (in strg any) returns datetime
xsd:double (in strg varchar) returns double precision
xsd:float (in strg varchar) returns float
xsd:integer (in strg varchar) returns integer
```

(assuming that the query contains the declaration: 'PREFIX xsd: <http://www.w3.org/2001/XMLSchema#>')

16.2.2. Query Constructs

Starting from Version 5.0, Virtuoso supports filtering RDF objects triples by a given predicate.

Examples

The boolean functions bif:contains, bif:xcontains, bif:xpath_contains and bif:xquery_contains can be used for objects that come from Linked Data Views as well as for regular "physical" triples. Each of these functions takes two arguments and returns a boolean value. The first argument is a local variable which should also be used as an object field in the group pattern where the filter condition is placed.

In order to execute the examples below please run these commands:

```
SQL>SPARQL CLEAR GRAPH <http://MyTest.com>;
DB.DBA.RDF_QUAD_URI_L ('http://MyTest.com', 'sxml1', 'p_all1', xtree_doc ('<Hello>world</Hello>'));
DB.DBA.RDF_QUAD_URI_L ('http://MyTest.com', 'sxml2', 'p_all2', xtree_doc ('<Hello2>world</Hello2>'));
DB.DBA.RDF_QUAD_URI_L ('http://MyTest.com', 'nonxml1', 'p_all3', 'Hello world');
VT_INC_INDEX_DB_DBA_RDF_OBJ();
DB.DBA.RDF_OBJ_FT_RULE_ADD ('http://MyTest.com', null, 'My test RDF Data');
```

bif:contains

```
SQL>SPARQL
SELECT *
FROM <http://MyTest.com>
WHERE { ?s ?p ?o . ?o bif:contains "world" };

s             p         o
VARCHAR       VARCHAR   VARCHAR
```

```
sxml1          p_all1    <Hello>world</Hello>
nonxml1        p_all3    Hello world
sxml2          p_all2    <Hello2>world</Hello2>

3 Rows. -- 20 msec.
```

bif:xcontains

```
SQL>SPARQL
SELECT *
FROM <http://MyTest.com>
WHERE { ?s ?p ?o . ?o bif:xcontains "//Hello[text-contains (., 'world')]" };
s                 p           o
VARCHAR           VARCHAR     VARCHAR
_______________________________________________________________________________

sxml1             p_all       <Hello>world</Hello>

1 Rows. -- 10 msec.
```

bif:xpath_contains

```
SQL>SPARQL
SELECT *
FROM <http://MyTest.com>
WHERE { ?s ?p ?o . ?o bif:xpath_contains "//*" };

s             p          o
VARCHAR       VARCHAR    VARCHAR
_______________________________________________________________________________

sxml1         p_all1     <Hello>world</Hello>
sxml2         p_all2     <Hello2>world</Hello2>

2 Rows. -- 20 msec.
```

bif:xquery_contains

```
SQL>SPARQL
SELECT *
FROM <http://MyTest.com>
WHERE { ?s ?p ?o . ?o bif:xquery_contains "//Hello2 , world" };

s             p          o
VARCHAR       VARCHAR    VARCHAR
_______________________________________________________________________________

sxml2         p_all2     <Hello2>world</Hello2>

1 Rows. -- 20 msec.
```

16.2.3. SPARQL Web Services & APIs

Introduction

The Virtuoso SPARQL query service implements the SPARQL Protocol for RDF (W3C Working Draft 25 January 2006) providing SPARQL query processing for RDF data available on the open internet.

The query processor extends the standard protocol to provide support for multiple output formats. At present this uses additional query parameters.

Supported features include:

- Support for GET and POST requests
- Support for a variety of transfer MIME-types, including RDF /XML and TURTLE
- Support for: *default-graph-uri*, *named-graph-uri*, *using-graph-uri*, *using-named-graph-uri*, *format* parameters

- Support for: *debug*, *timeout*, *maxrows*, *qtxt*, *query* parameters
- Support for a variety of query types including CONSTRUCT, ASK, DESCRIBE

Virtuoso also supports /sparql-graph-crud/ web service endpoint that implements the current draft of W3C SPARQL Graph Update protocol . Both /sparql /sparql-graph-crud/ endpoints use the same SPARQL user account, so this user should be member of SPARQL_UPDATE group in order to modify data via Graph Update protocol. Note that /sparql/ endpoint has /sparql-auth/ variant that uses web authentication. Similarly, /sparql-graph-crud/ has /sparql-graph-crud-auth/ variant. As soon as user is member of SPARQL_UPDATE group, she/he can modify the stored data via /sparql-graph-crud-auth/ as well as via /sparql-auth/ . The /sparql-graph-crud/ endpoint is primarily for serving requests from applications, not for manual interactions via browser. See more information in our SPARQL Authentication section.

Service Endpoint

Virtuoso uses the pre-assigned endpoints "/sparql" and "/SPARQL" as the defaults for exposing its REST based SPARQL Web Services.

The port number associated with the SPARQL services is determined by the 'ServerPort' key value in the '[HTTPServer]' section of the virtuoso.ini file. Thus, if the Virtuoso instance is configured to listen at a none default port e.g. 8890, the SPARQL endpoints would be accessible at http://example.com:8890/sparql/.

The SPARQL endpoint supports both GET and POST requests. The client chooses between GET and POST automatically, using the length of query text as the criterion. If the SPARQL endpoint is accessed without any URL and requisite SPARQL protocol parameters, an interactive HTML page for capturing SPARQL input will be presented.

Customizing SPARQL Endpoint Page

The SPARQL Endpoint Page can now be customized using a xsl stylesheet.

This works by adding the following line with isql:

```
SQL> registry_set ('sparql_endpoint_xsl', 'http://host:port/path/isparql.xsl');
```

where obviously host, port, path and the name isparql.xsl can be set to anything.

SPARQL Protocol Extensions

Request Parameters

Table 16.1. Request Parameters List

Parameter	Notes	Required?
service	Service URI such as 'http://example.com/sparql/'	Yes
query	Text of the query	Yes
dflt_graph	Default graph URI (string or NULL)	No
named_graphs	Vector of named graphs (or NULL to prevent overriding named graphs specified in the query)	Yes
req_hdr	Additional HTTP headers that should be passed to the service, e.g. 'Host: ...'	No
maxrows	Limit on the numbers of rows that should be returned (the actual size of the result set may differ)	No
xslt-uri	Absolute URL of any XSLT stylesheet file to be applied to the SPARQL query results	No
timeout	Timeout for "anytime" query execution, in milliseconds, values less than 1000 are ignored; see Anytime Queries for more details	No
debug	If set to on, SPARQL Compiler will check if all variables are declared, and if there is variable that is not declared, an error will be raised	No

Response Codes

If the query is a CONSTRUCT or a DESCRIBE then the result set consists of a single row and a single column. The value inside is a dictionary of triples in 'long valmode'. Note that the dictionary object cannot be sent to a SQL client, say, via ODBC. The client may lose the database connection trying to fetch a result set row that contains a dictionary object. This disconnection does not disrupt the server, so the client may readily reconnect to the server, but the disconnected transaction will have been rolled

back.

See Also:

- Virtuoso ODBC RDF extensions for SPASQL

Response Format

All the SPARQL protocol standard MIME types are supported by a SPARQL web service client. Moreover, SPARQL web service endpont supports additional MIME types and in some cases additional query types for standard MIME types.

Server Response Formats

Table 16.2. Server Response Formats

Content-Type	SPARQL query type	Description
'application/sparql-results+xml'	SELECT, ASK	Canonical XML presentation of SPARQL result set
'text/rdf+n3'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle
'text/rdf+ttl'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle
'text/rdf+turtle'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle
'text/turtle'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle
'text/n3'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle
'application/turtle'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle
'application/x-turtle'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle
'application/x-nice-turtle'	SELECT, ASK, CONSTRUCT, DESCRIBE	Turtle, like above, but the server will try to use "list" and "[...]" notations to make the document easier to read. This formatting is a slow procedure so long results will be formatted as plain Turtle.
'text/rdf+nt'	SELECT	Format for NT (each triple is printed separately without abbreviations)
'text/plain'	SELECT	Format for NT (each triple is printed separately without abbreviations)
'text/ntriples'	SELECT, CONSTRUCT, DESCRIBE	Format for NT (each triple is printed separately without abbreviations)
'application/x-trig'	SELECT, CONSTRUCT, DESCRIBE	TriG syntax for result sets, triples and quads (or sets of graphs with triples). While it is not used for quads, the output is same as for Turtle.
'application/rdf+xml'	SELECT, CONSTRUCT, DESCRIBE	Canonical RDF/XML presentation
'application/soap+xml'	SELECT	SOAP XML
'application/soap+xml;11'	SELECT	SOAP XML
'text/html'	SELECT	HTML document for plain browsing; it's a TABLE for result set and HTML with micro-data for triples
'text/md+html'	SELECT, CONSTRUCT, DESCRIBE	HTML with microdata; for triples only
'text/microdata+html'	SELECT, CONSTRUCT, DESCRIBE	HTML with microdata; for triples only
'text/x-html+ul'	SELECT, CONSTRUCT, DESCRIBE	HTML with triples grouped into hierarchical list

Content-Type	SPARQL query type	Description
'text/x-html+tr'	SELECT, CONSTRUCT, DESCRIBE	HTML with triples in form of a table
'application/vnd.ms-excel'	SELECT	HTML table for loading data into stylesheets
'text/csv'	SELECT, CONSTRUCT, DESCRIBE	Comma-separated values
'text/tab-separated-values'	SELECT	Tab-separated values
'application/javascript'	SELECT	JavaScript data fragment
'application/json'	SELECT	JSON
'application/sparql-results+json'	SELECT, ASK	JSON result set
'application/odata+json'	SELECT, ASK, CONSTRUCT, DESCRIBE	JSON in ODATA style
'application/microdata+json'	SELECT, CONSTRUCT, DESCRIBE	Microdata as JSON; for triples only
'application/rdf+json'	CONSTRUCT, DESCRIBE	JSON in TALIS style; for triples only
'application/x-rdf+json'	CONSTRUCT, DESCRIBE	JSON in TALIS style; for triples only
'application/x-json+ld'	CONSTRUCT, DESCRIBE	JSON in Linked Data style; for triples only
'application/ld+json'	CONSTRUCT, DESCRIBE	JSON in Linked Data style; for triples only
'text/cxml'	SELECT, CONSTRUCT, DESCRIBE	CXML output for rendering in Pivot Viewer of MS SilverLight?. Result sets and triples are handled in different ways.
'text/cxml+qrcode'	SELECT,CONSTRUCT, DESCRIBE	CXML output with QRcode imprinted into each picture; for result sets and triples
'application/atom+xml'	SELECT, CONSTRUCT, DESCRIBE	Atom-style XML
'application/xhtml+xml'	SELECT	RDFa placed into XHTML; for triples only

Client Response Formats

Table 16.3. Client Response Formats

Content-Type	SPARQL query type	Description
'application/sparql-results+xml'	SELECT, ASK	Canonical XML presentation of SPARQL result set
'text/rdf+n3'	CONSTRUCT, DESCRIBE	Turtle
'text/rdf+ttl'	CONSTRUCT, DESCRIBE	Turtle
'text/rdf+turtle'	CONSTRUCT, DESCRIBE	Turtle
'text/turtle'	CONSTRUCT, DESCRIBE	Turtle
'text/n3'	CONSTRUCT, DESCRIBE	Turtle
'application/turtle'	CONSTRUCT, DESCRIBE	Turtle
'application/x-turtle'	CONSTRUCT, DESCRIBE	Turtle
'application/rdf+xml'	CONSTRUCT, DESCRIBE	Canonical RDF/XML presentation

The current implementation does not support returning the results of SELECT as RDF/XML or 'sparql-results-2'.

If the HTTP header returned by the remote server does not contain a 'Content-Type' line, the client may guess MIME type from the text of the returned body.

Error messages returned from the service are returned as XML documents, using the MIME type application/xml. The documents consist of a single element containing an error message.

Additional Response Formats -- SELECT

Use the format parameter to select one of the following alternate output formats:

Table 16.4. Additional Response formats list -- SELECT

Format Value	Description	Mimetype
HTML	The result is a HTML document containing query summary and tabular results. The format is human-readable but not intended for using by applications because it makes strings undistinguishable from IRIs and loses other details such as exact datatypes of returned values.	text/html
json	Two separate MIME types exist for JSON: JSON serialization of results is 'application/sparql-results+json' and confirms to the draft specification "Serializing SPARQL Query Results in JSON". JSON serialization of triples is 'application/rdf+json' and interoperable with Talis. Sometimes a client needs a JSON but it does not know the type of query it sends to Virtuoso web service endpoint. In this case the client can specify either one MIME-type 'application/json' or both 'application/sparql-results+json' and 'application/rdf+json' in the "Accept" header line and Virtuoso will chose the appropriate one automatically. Similar trick works for other sorts of result types: Virtuoso inspects the whole "Accept" header line to find out the most appropriate return type for the given query.	application/sparql-results+json
json		application/rdf+json
js	Javascript serialization of results generates an HTML table with the CSS class sparql. The table contains a column indicating row number and additional columns for each query variable. Each query solution contributes one row of the table. Unbound variables are indicated with a non-breaking space in the appropriate table cells.	application/javascript
table		text/html
XML		text/html
TURTLE		text/html

Additional Response Formats -- CONSTRUCT & DESCRIBE

Example output of DESCRIBE in rdf+json serialization format

1. Go to the sparql endpoint at http://host:port/sparql, for ex. at http://dbpedia.org/sparql
2. Enter query in the "Query text" area, for ex.:

```
DESCRIBE <http://dbpedia.org/resource/%22S%22_Bridge_II>
```

3. Select for "Display Results As": JSON
4. Click "Run Query" button.
5. As result should be produced the following output:

```
{
  { 'http://dbpedia.org/resource/%22S%22_Bridge_II' : { 'http://www.w3.org/1999/02/22-rdf-syntax-n
      { 'type' : 'uri', 'value' : 'http://dbpedia.org/ontology/Resource' } ,
      { 'type' : 'uri', 'value' : 'http://dbpedia.org/ontology/HistoricPlace' } } ,
    { 'http://dbpedia.org/ontology/added' : { 'type' : 'literal', 'value' : '1973-04-23' , 'dataty
    { 'http://www.w3.org/2003/01/geo/wgs84_pos#lat' : { 'type' : 'literal', 'value' : 39.993057250

Example output of CONSTRUCT in rdf+json serialization format

1. Go to the sparql endpoint at http://host:port/sparql, for ex. at http://dbpedia.org/sparql
2. Enter query in the "Query text" area, for ex.:

```
CONSTRUCT
{
 ?s a ?Concept .
}
WHERE
{
 ?s a ?Concept .
}
LIMIT 10
```

3. Select for "Display Results As": JSON
4. Click "Run Query" button.
5. As result should be produced the following output:

```
{
  { 'http://dbpedia.org/ontology/Place' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type' : {
  { 'http://dbpedia.org/ontology/Area' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type' : { '
  { 'http://dbpedia.org/ontology/City' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type' : { '
  { 'http://dbpedia.org/ontology/River' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type' : {
  { 'http://dbpedia.org/ontology/Road' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type' : { '
  { 'http://dbpedia.org/ontology/Lake' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type' : { '
  { 'http://dbpedia.org/ontology/LunarCrater' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type
  { 'http://dbpedia.org/ontology/ShoppingMall' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#typ
  { 'http://dbpedia.org/ontology/Park' : { 'http://www.w3.org/1999/02/22-rdf-syntax-ns#type' : { '
  { 'http://dbpedia.org/ontology/SiteOfSpecialScientificInterest' : { 'http://www.w3.org/1999/02/2
}
```

For interoperability with clients that were developed before current versions of SPARQL protocol and format specs are issued, Virtuoso supports some obsolete variants of standard MIME types. 'text/rdf+n3', 'text/rdf+ttl', 'application/turtle' and 'application/x-turtle' are understood for TURTLE output, 'application/x-rdf+json' and 'application/rdf+json' are for "Serializing SPARQL Query Results in JSON". When a client specifies obsolete MIME type but not its standard variant, an obsolete variant is returned for interoperability.

Strict checking of void variables

To set SPARQL Endpoint to check if all variables in a given query are declared correctly, one should hatch the the Options "Strict checking of void variables" check-box. In that case, if a variable declaration is missing, i.e. not included in the SPARQL Query WHERE clause, then an error will be raised. For example, on attempt to execute the following query:

```
--      Options "Strict checking of void variables" check-box is checked:
select ?y
where
 {
  ?s ?p ?o
 }
```

since the variable `?y` is not declared, the following error will be raised:

```
Virtuoso 37000 Error SP031: SPARQL compiler:
Variable 'y' is used in the query result set but not assigned

SPARQL query:

#output-format:text/html
define sql:signal-void-variables 1 define sql:gs-app-callback "ODS" select ?y
where
{
?s ?p ?o
}
```

View Results Page of SPARQL Query Execution

To view SPARQL Endpoint Results page of SPARQL query execution should be used the parameter *query* i.e the SPARQL Protocol URL should look like:

```
http://cname/sparql?default-graph-uri=&query=...
```

Example

Suppose the following simple query:

```
SELECT *
WHERE
  {
    ?s ?p ?o
  }
LIMIT 10
```

See this example link against Virtuoso Demo Server SPARQL Endpoint with SPARQL Protocol URL.

View Editor Page of SPARQL Query

To view the SPARQL Endpoint editor page of SPARQL query execution should be used the parameter *qtxt* i.e the SPARQL Protocol URL should look like:

```
http://cname/sparql?default-graph-uri=&qtxt=...
```

Example

Suppose the following simple query:

```
SELECT *
WHERE
  {
    ?s ?p ?o
  }
LIMIT 10
```

Suppose also this results page link against Virtuoso Demo Server SPARQL Endpoint with SPARQL Protocol URL.

Replace the parameter name *query* with *qtxt* .

Access the new link , which should present the SPARQL Endpoint Editor page with "Query Text" area filled in with the SPARQL Query from above.

Virtuoso/PL APIs

Virtuoso also provides SPARQL protocol client APIs in Virtuoso PL, so you can communicate with SPARQL Query Services from Virtuoso stored procedures. The APIs are as follows:

Table 16.5. Virtuoso/PL APIs

API	Notes
DB.DBA.SPARQL_REXEC	Behaves like DBA.SPARQL_EVAL, but executes the query on the specified server. The procedure does not return anything. Instead, it creates a result set.
DB.DBA.SPARQL_REXEC_TO_ARRAY	Behaves like DBA.SPARQL_EXEC_TO_ARRAY(), but executes the query on the specified server. The function returns a vector of rows, where every row is represented by a vector of field values.
DB.DBA.SPARQL_REXEC_WITH_META	Has no local SPARQL_EVAL analog. It produces not only an array of result rows together with an array of result set metadata in a format used by the exec() function.

SPARQL Anytime Queries

Starting with version 6, Virtuoso offers a partial query evaluation feature that guarantees answers to arbitrary queries within a fixed time. This is intended for use in publicly available SPARQL or SQL end points on large databases. This enforces a finite duration to all queries and will strive to return meaningful partial results. Thus this provides the same security as a transaction timeout but will be more user friendly since results will generally be returned, also for aggregate queries. Outside of a public query service, this may also be handy when exploring a large data set with unknown properties.

The feature is activated with the statement

```
set result_timeout == <expression>;
```

Find more detailed information in the Anytime Queries section.

Example Dump arbitrary query result as N-Triples

Assume the following arbitrary query:

```
SPARQL define output:format "NT"
CONSTRUCT { ?s a ?t }
FROM virtrdf:
WHERE { ?s a ?t };
```

For iteration over result-set of an arbitrary query, use `exec_next()` in a loop that begins with `exec()` with cursor output variable as an argument and ends with `exec_close()` after it is out of data.

Service Endpoint Security

Earlier releases of Virtuoso secured the SPARQL endpoint via privileges assigned to the service- specific SQL user account "SPARQL". This account was optionally granted "SPARQL_SELECT" or "SPARQL_UPDATE" roles. By default only the "SPARQL_SELECT" role was assigned, enabling all users to at least perform SELECT queries. The "SPARQL_UPDATE" role must be granted to allow updates to the Quad Store - a pre-requisite for the Virtuoso Sponger services to be functional i.e. to allow the Sponger to populate and update the Quad Store. In Virtuoso release 5.0.7, there is a new "SPARQL_SPONGE" role which can be assigned specifically to allow Sponger services to update the Quad Store but not SPARQL users via the SPARQL endpoint.

Restricting a user's access to specific graphs can be done using Virtuoso Graph security functionality, via one of the Virtuoso Data Access APIs: ODBC, JDBC, ADO.Net or PL code.

See Also:

- Virtuoso ODBC RDF extensions for SPASQL

For example, users of OpenLink Data Space (ODS) applications are restricted in the RDF graphs accessible to them as follows:

```
DB.DBA.TABLE_DROP_POLICY ('DB.DBA.RDF_QUAD', 'S');

create procedure DB.DBA.RDF_POLICY (in tb varchar, in op varchar)
{
 declare chost, ret varchar;
 chost := DB.DBA.WA_CNAME ();
 ret := sprintf ('(ID_TO_IRI (G) NOT LIKE \'http://%s/dataspace/%%/private#\' ' ||
 'OR G = IRI_TO_ID (sprintf (\'http://%s/dataspace/%%U/private#\', USER)))', chost, chost);
 return ret;
}
;

grant execute on DB.DBA.RDF_POLICY to public;

DB.DBA.TABLE_SET_POLICY ('DB.DBA.RDF_QUAD', 'DB.DBA.RDF_POLICY', 'S');
```

where DB.DBA.WA_CNAME () is an ODS function returning the default host name.

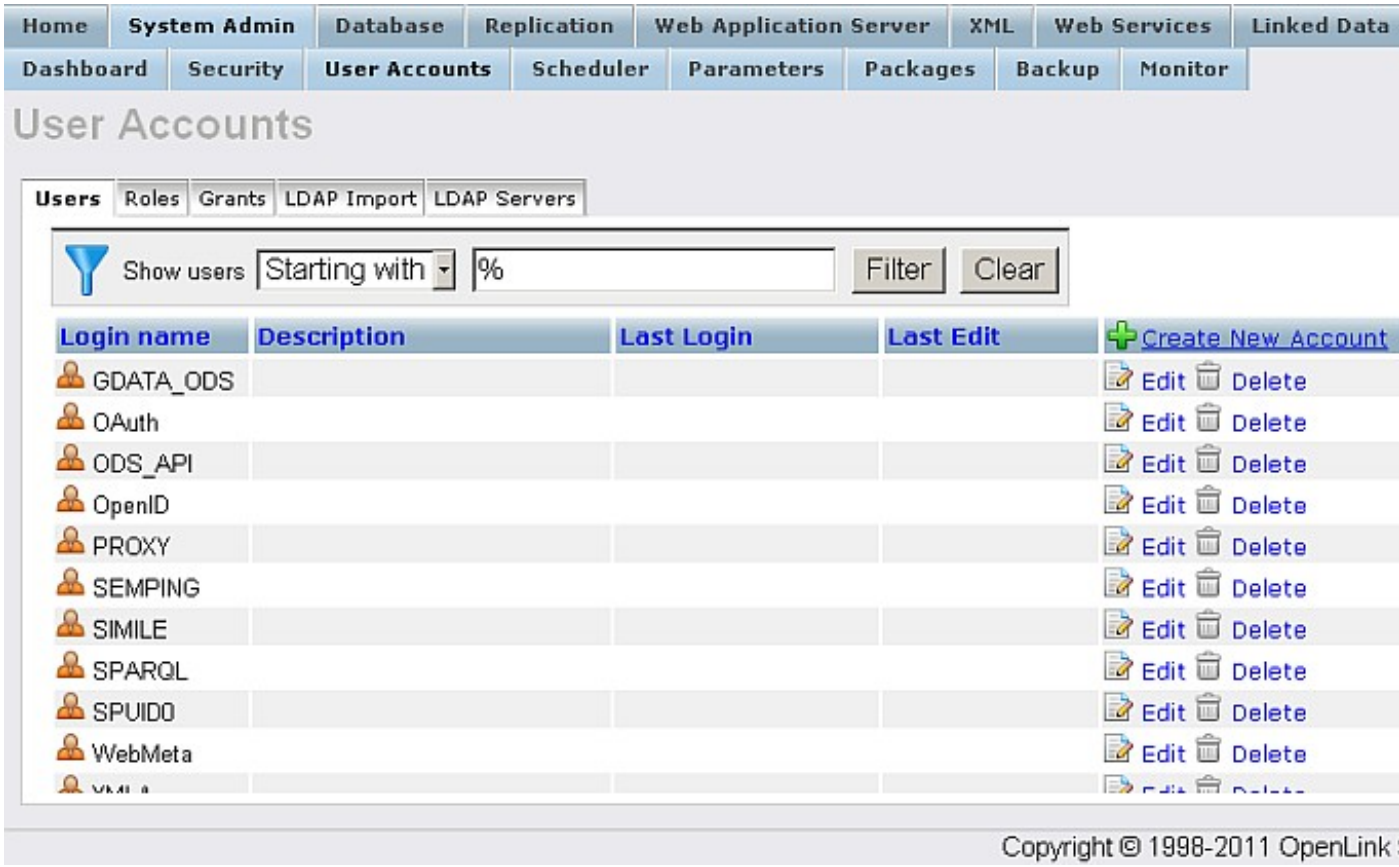
The effect of this policy is to restrict user 'user' to the graph http://cname/dataspace/user/private#

SPARQL Auth Endpoint Usage Example

Virtuoso reserves the path '/sparql-auth/' for a SPARQL service supporting authenticated SPARUL. This endpoint allows specific SQL accounts to perform SPARUL over the SPARQL protocol. To be allowed to login via SQL or ODBC and update physical triples, a user must be granted "SPARQL_UPDATE" privileges. To grant this role:

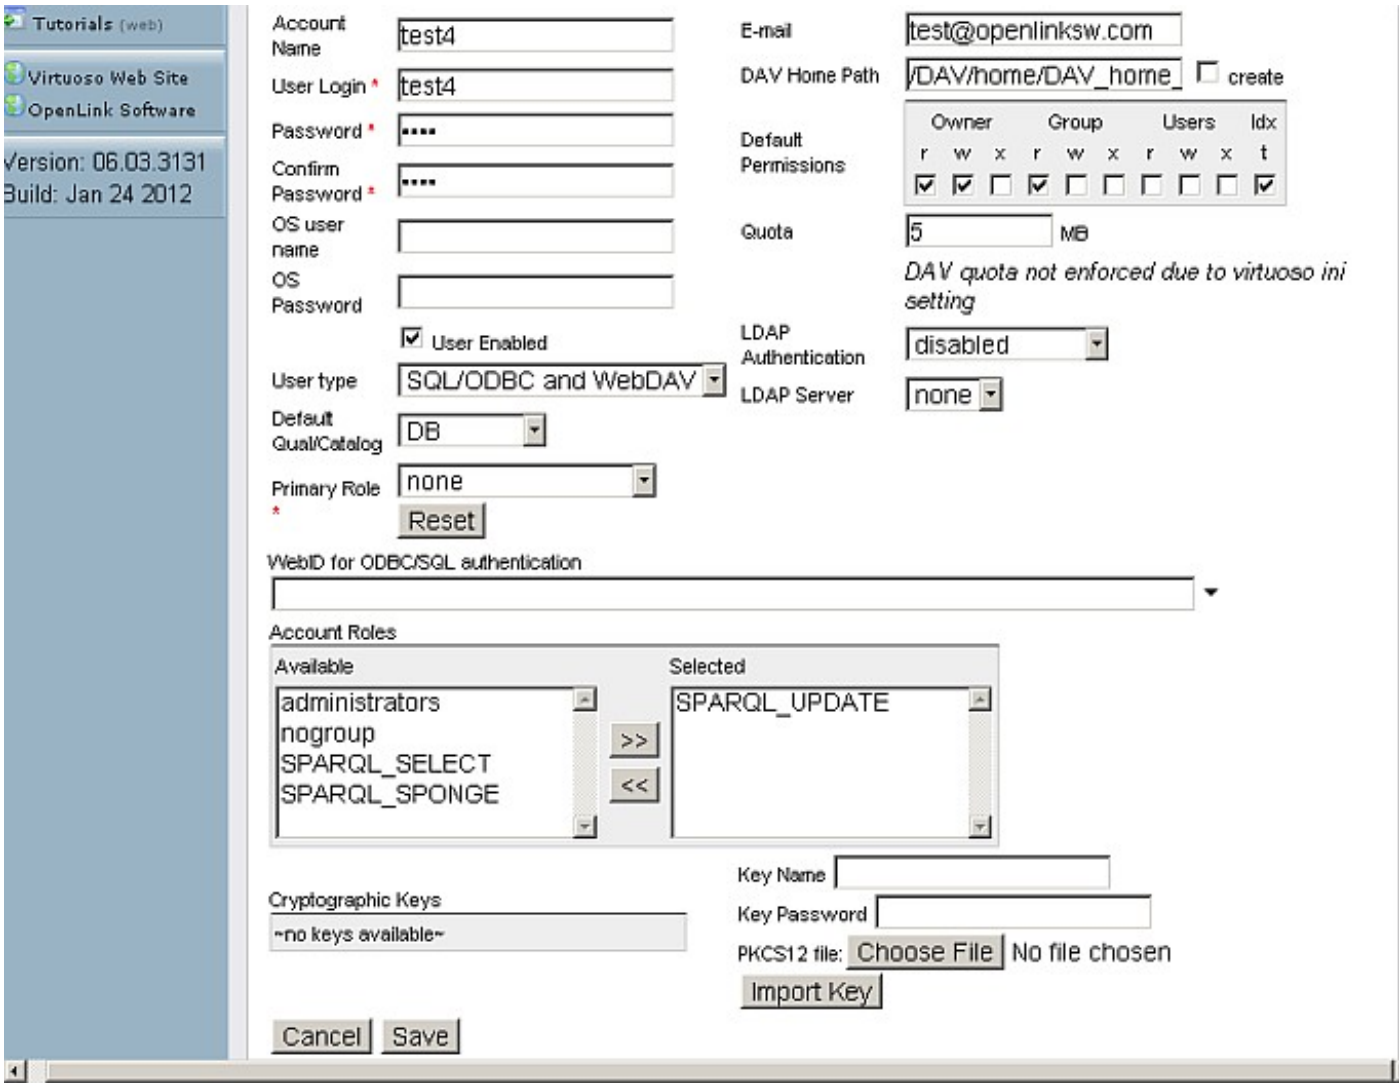
1. Go to the Virtuoso administration UI i.e. http://host:port/conductor
2. Login as user dba
3. Go to System Admin->User Accounts->Users

Figure 16.1. Conductor UI



4. Click the link "Edit"
5. Set "User type" to "SQL/ODBC Logins and WebDAV".
6. Select from the list of available Account Roles "SPARQL_UPDATE" role and click the ">>" button so to add it to the right-hand list.

7. **Figure 16.2. Conductor UI**



8. Click the "Save" button.

Note that if a table is used in an Linked Data View, and this table is not granted to SPARQL_SELECT permission (or SPARQL_UPDATE, which implicitly confers SPARQL_SELECT), then all SELECTs on a graph defined by an Linked Data View will return an access violation error as the user account has no permissions to read the table. The user must have appropriate privileges on all tables included in an Linked Data View in order to be able to select on *all* graphs.

Managing a SPARQL Web Service Endpoint

Virtuoso web service endpoints may provide different default configurations for different host names mentioned in an HTTP request. Host name configuration for SPARQL web service endpoints can be managed via the table *DB.DBA.SYS_SPARQL_HOST* .

```
create table DB.DBA.SYS_SPARQL_HOST (
  SH_HOST       varchar not null primary key, -- host mask
  SH_GRAPH_URI varchar,                 -- default graph uri
  SH_USER_URI   varchar,                  -- reserved for any use in applications
  SH_BASE_URI varchar,                  -- for future use (not used currently) to set BASE in sparql quer
  SH_DEFINES long varchar,              -- additional defines for requests
  PRIMARY KEY (SH_HOST)
)
```

You can find detailed descriptions of the table columns here . Also, please read these notes on managing public web service endpoints.

Authentication

Virtuoso 5.0.7 introduced a new "SPARQL_SPONGE" role which can be assigned specifically for controlling Sponger middleware services which perform writes and graph creation in the RDF Quad Store. This role only allows updates through the Sponger. Quad Store updates via any other route require granting the SPARQL_UPDATE role.

Virtuoso 5.0.11 onwards added three new methods for securing SPARQL endpoints that include:

- SQL authentication
- OAuth
- WebID Protocol based authentication

Each of these authentication methods is associated with a purpose specific default SPARQL endpoint along the following lines:

- http://<cname>/sparql-auth (SQL authentication)
- http://<cname>/sparql-oauth (OAuth)
- http://<cname>/sparql-graph-crud-auth (OAuth CRUD)
- https://<cname>/sparql and https://<cname>/sparql-webid (WebID Protocol)

Note: sparql-ssl is alias of sparql-webid.

The Virtuoso Authentication Server offers a UI with options for managing:

- Application keys and protected SPARQL endpoints: OAuth provides a secure data transmission level mechanism for your SPARQL endpoint. It enables you to interact securely with your RDF database from a variety of locations. It also allows you to provide controlled access to private data to selected user profiles.
- WebID Protocol ACLs: WebID Protocol is an implementation of a conceptual authentication and authorization protocol that links a Web ID to a public key to create a global, decentralized/distributed, and open yet secure authentication system that functions with existing browsers.

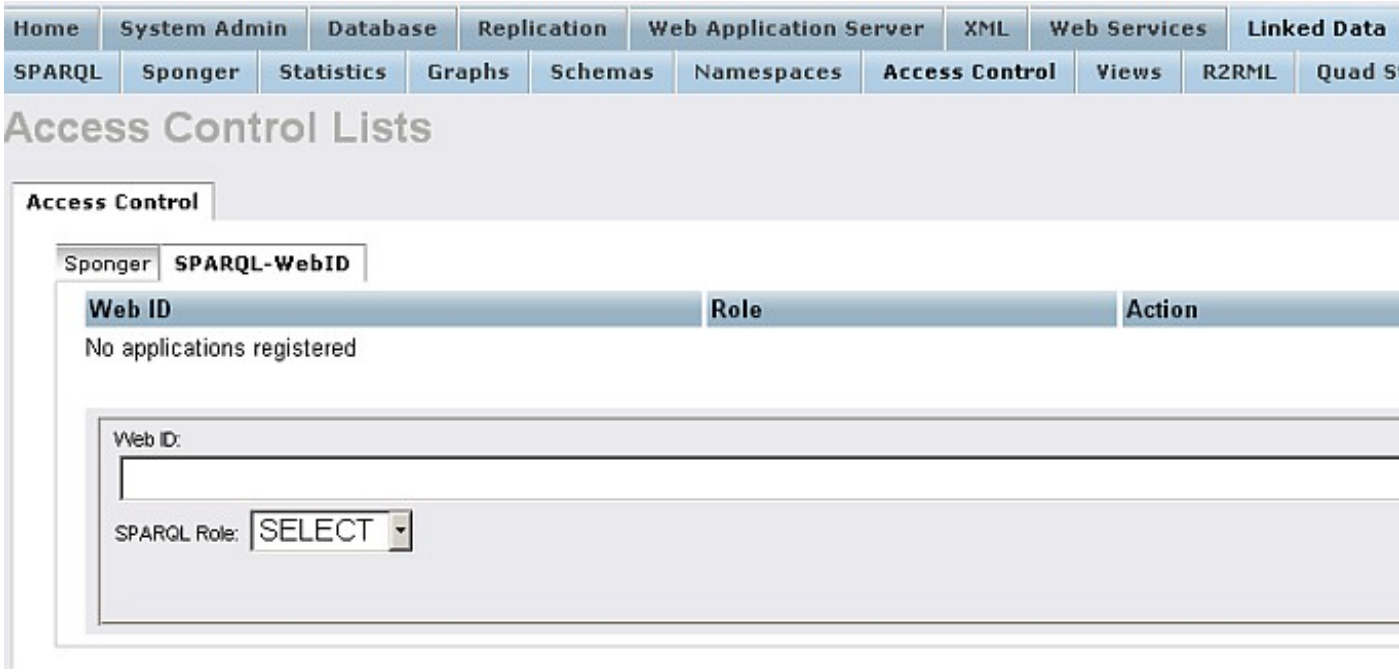
Virtuoso Authentication Server can be installed by downloading and installing the conductor_dav.vad package.

The Authentication UI is accessible from the Conductor UI -> Linked Data -> Access Control -> SPARQL-WebID. Here is sample scenario:

SPARQL-WebID Authentication Example

1. Download and install the conductor_dav.vad package.
2. Generate an X.509 Certificate hosted WebID .
3. Go to http://<cname>:<port>/conductor, where <cname>:<port> are replaced by your local server values.
4. Log in as user "dba" or another user with DBA privileges.
5. Go to Linked Data -> Access Controls -> SPARQL-WebID:

Figure 16.3. SPARQL-WebID

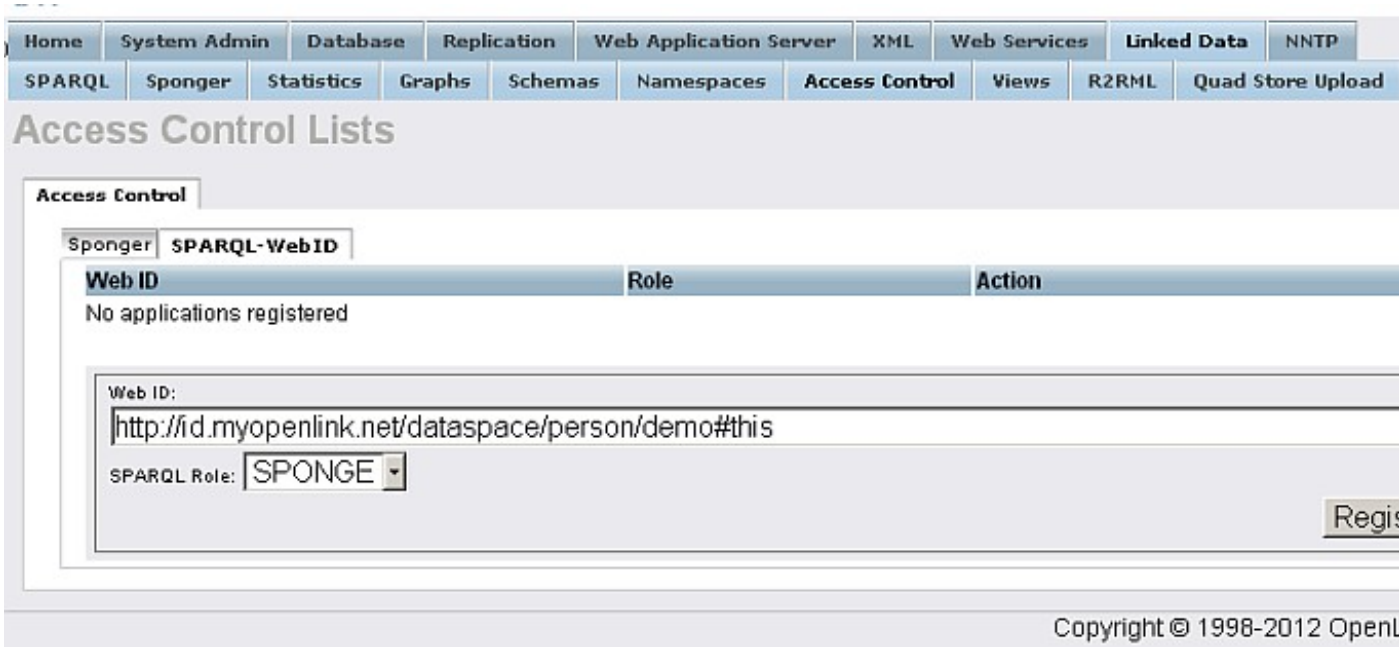


6. Enter in the presented form Web ID for ex.:

   ```
   http://id.myopenlink.net/dataspace/person/demo#this
   ```

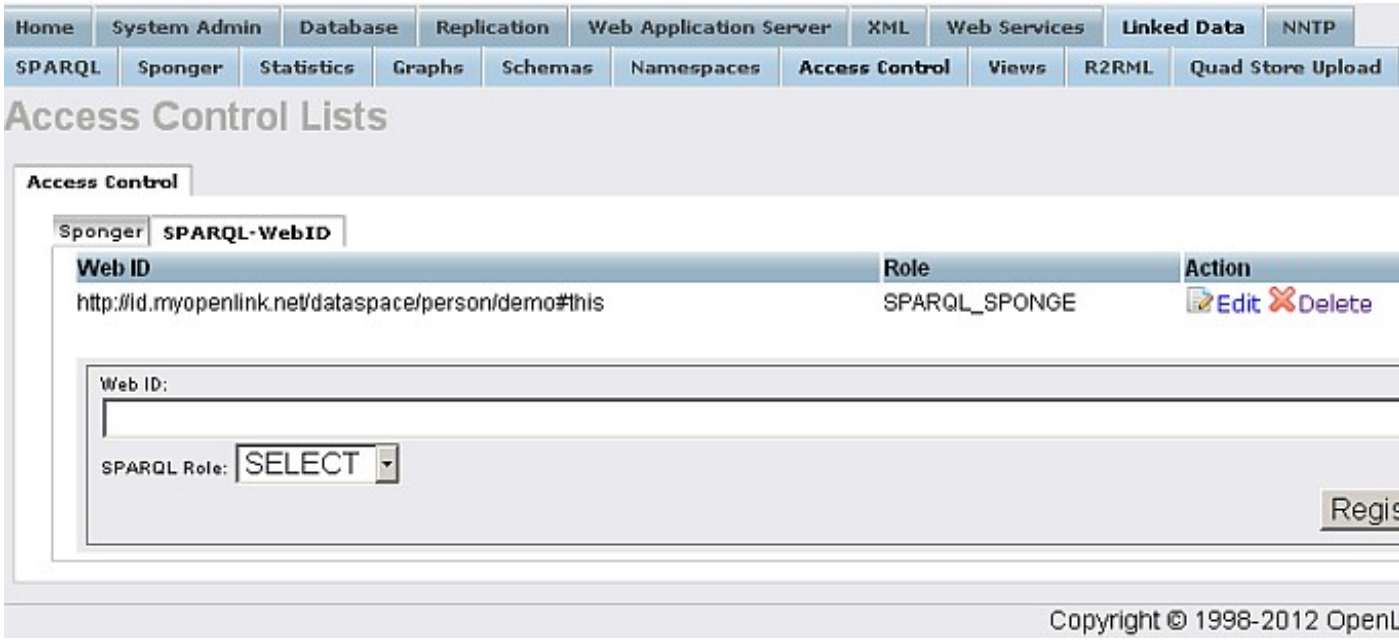
   and select "SPARQL Role" for ex. "Sponge".

Figure 16.4. SPARQL-WebID



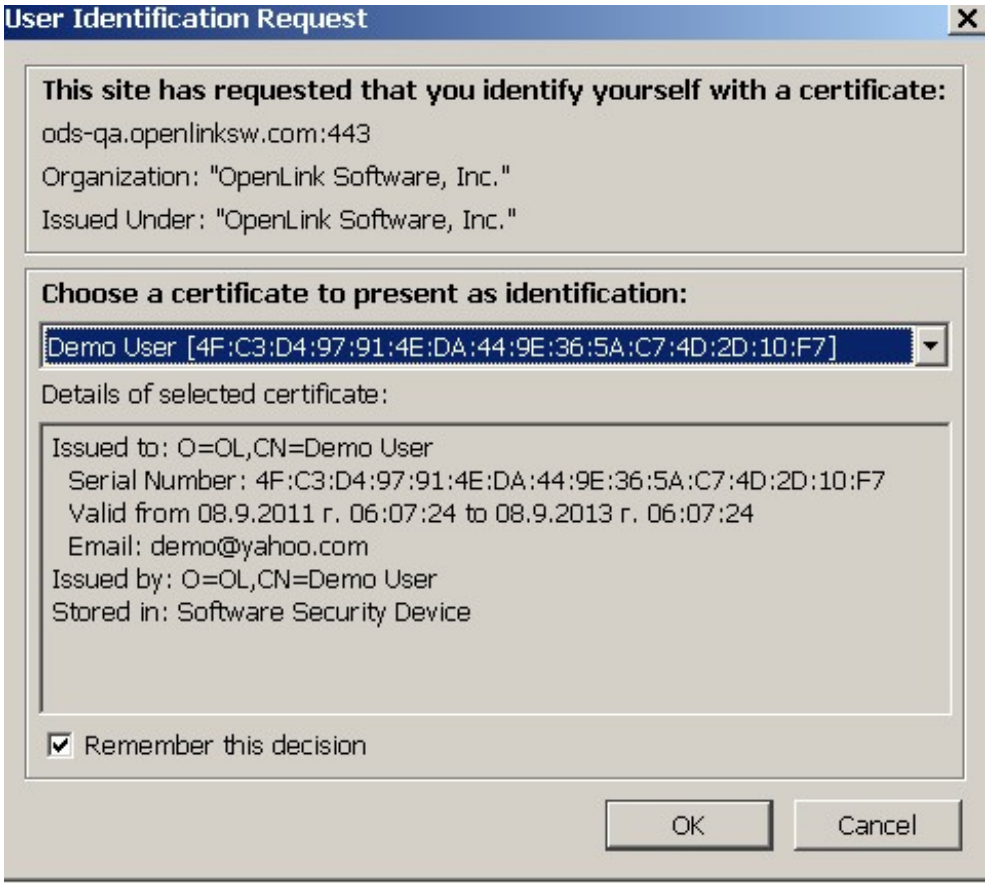
7. Click the "Register" button.
8. As result the WebID Protocol ACLs will be created:

Figure 16.5. SPARQL-WebID



9. Go to the SPARQL-WebID endpoint https://<cname>:<port>/sparql-webid
10. Select the user's certificate from above:

Figure 16.6. SPARQL-WebID



11. As result the SPARQL Query UI will be presented:

Figure 16.7. SPARQL-WebID

12. Execute sample query and view the results:

Figure 16.8. SPARQL-WebID

SPARQL OAuth Endpoint

OAuth provides a secure data transmission level mechanism for your SPARQL endpoint. It enables you to interact securely with your RDF database from a variety of locations. It also allows you to provide controlled access to private data to selected users.

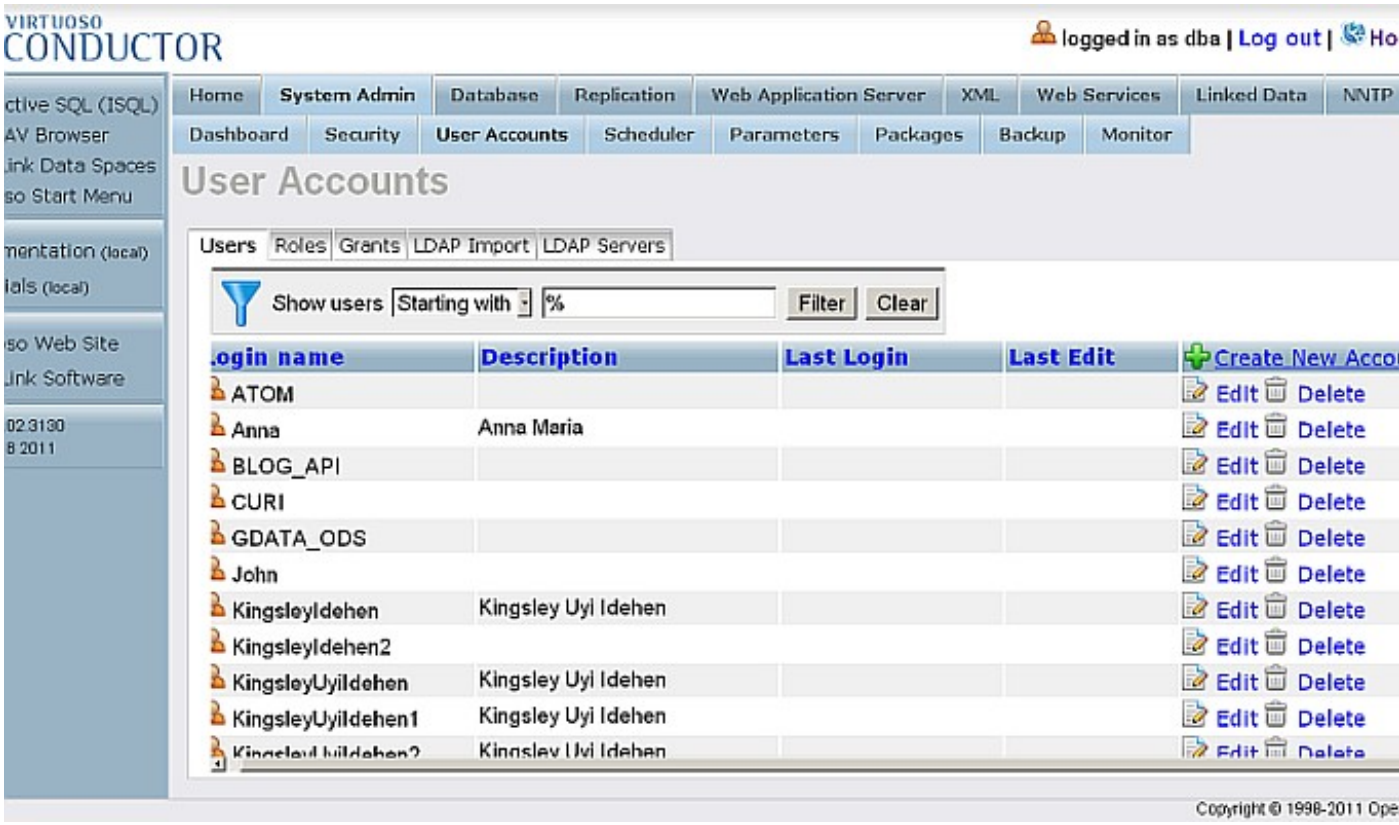
Virtuoso OAuth Server can be installed by downloading and installing the ods_framework_dav.vad package. The OAuth UI is accessible from the URL http://cname:port/oauth

A user must have SQL privileges in order to run secured SPARQL statements.

Here is a sample scenario:

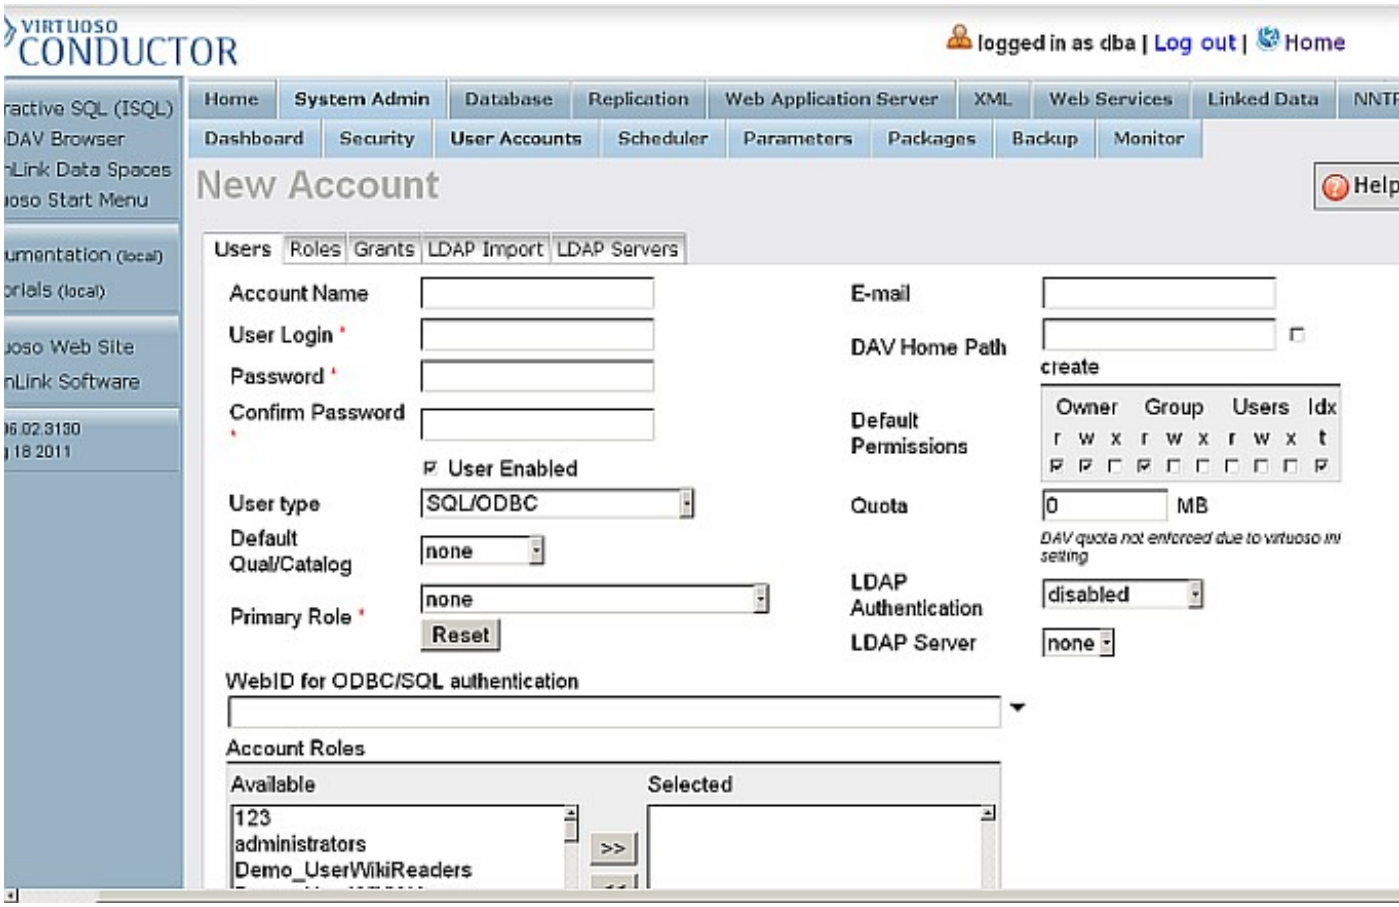
1. Download and install the conductor_dav.vad and ods_framework_dav.vad packages.
2. Generate an X.509 Certificate hosted WebID .
3. Go to http://<cname>:<port>/conductor, where <cname>:<port> are replaced by your local server values.
4. Log in as user "dba" or another user with DBA privileges.
5. Go to System Admin->User Accounts:

Figure 16.9. SPARQL OAuth Endpoint



6. Click "Create New Account":

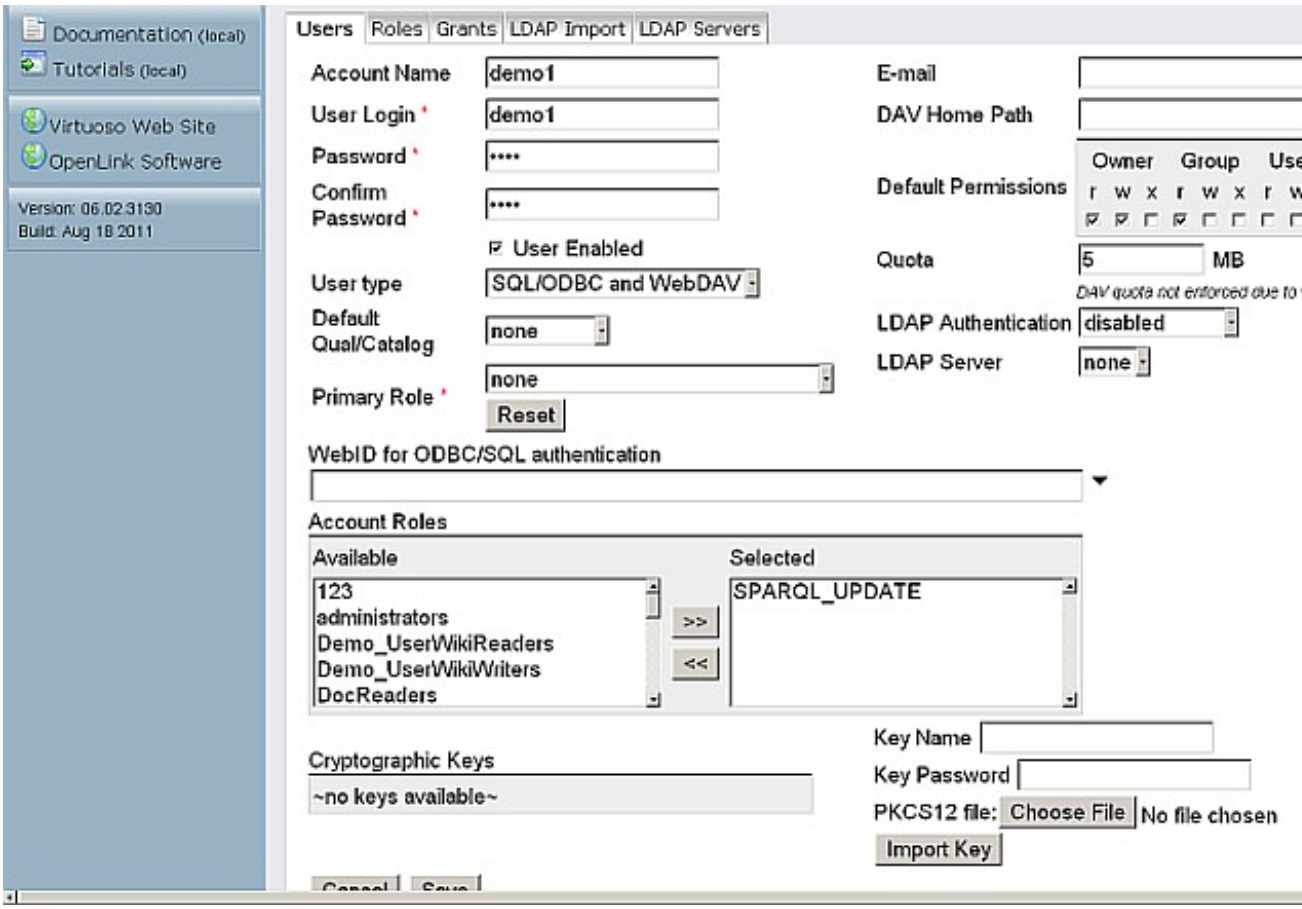
Figure 16.10. SPARQL OAuth Endpoint



7. In the presented form enter respectively:

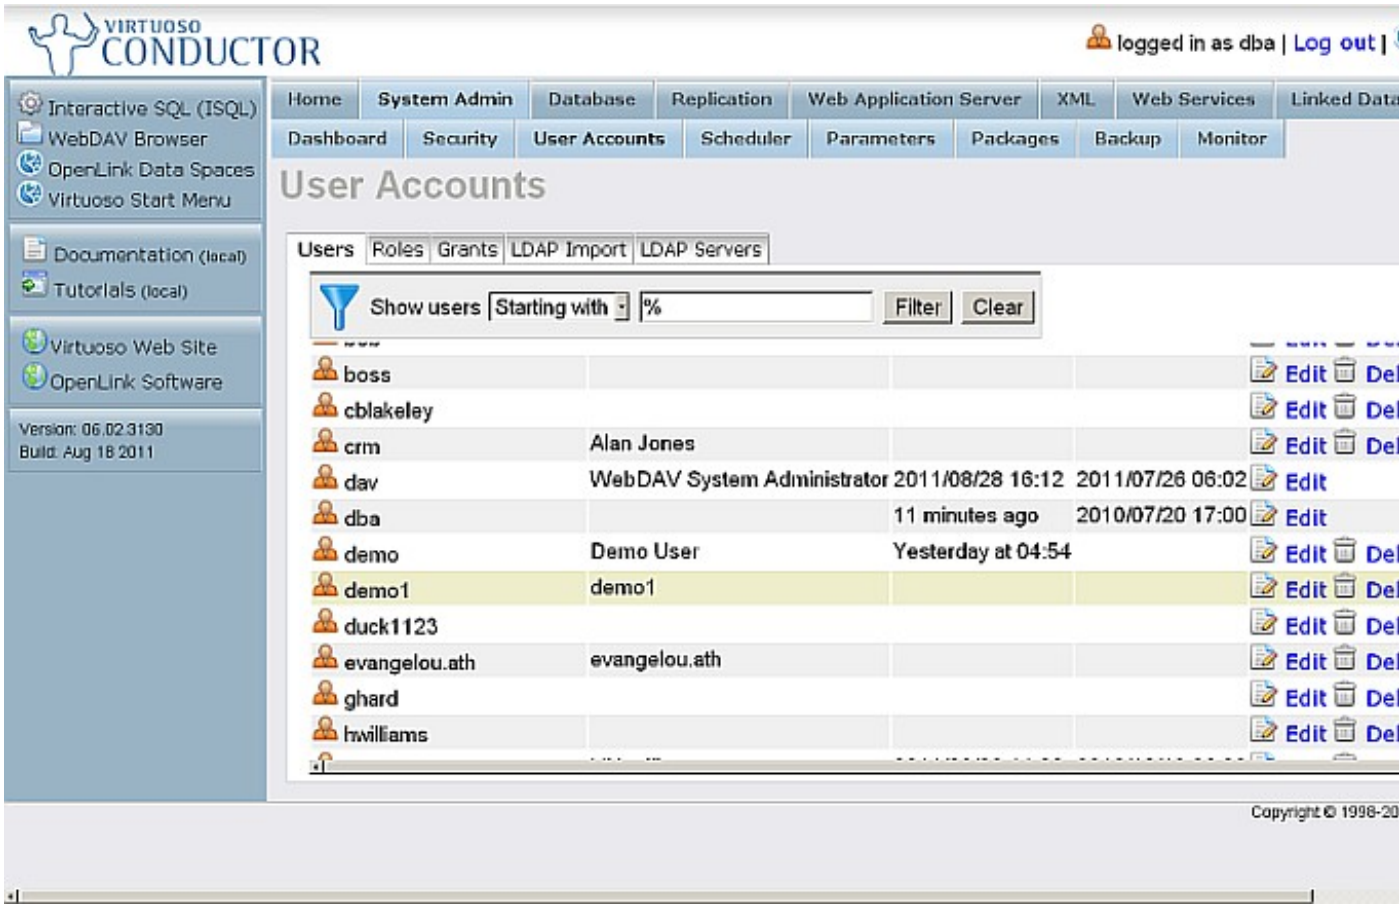
a. Account name, for ex:demo1; a password and then confirm the password;
b. User type: SQL/ODBC and WebDAV;
c. Account role: SPARQL_UPDATE

Figure 16.11. SPARQL OAuth Endpoint



8. Click the "Save" button.
9. The created user should be shown in the list of registered users:

Figure 16.12. SPARQL OAuth Endpoint

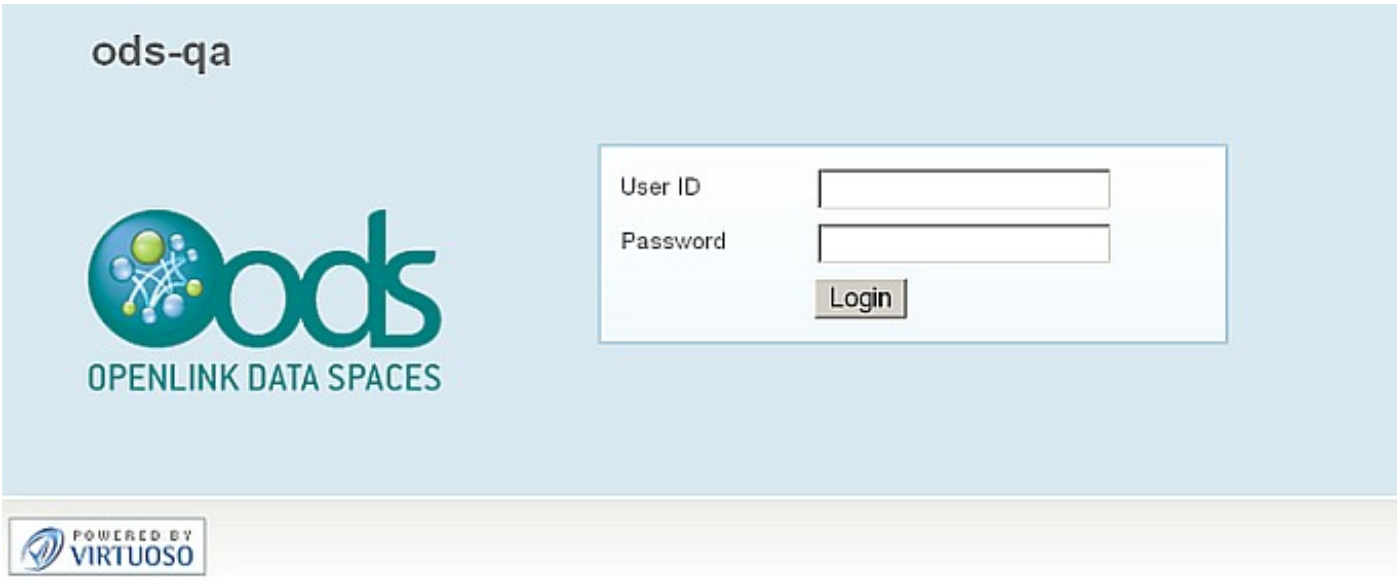


10. Go to http://<cname>:<port>/oauth/, where <cname>:<port> are replaced by your local server values.

Figure 16.13. SPARQL OAuth Endpoint

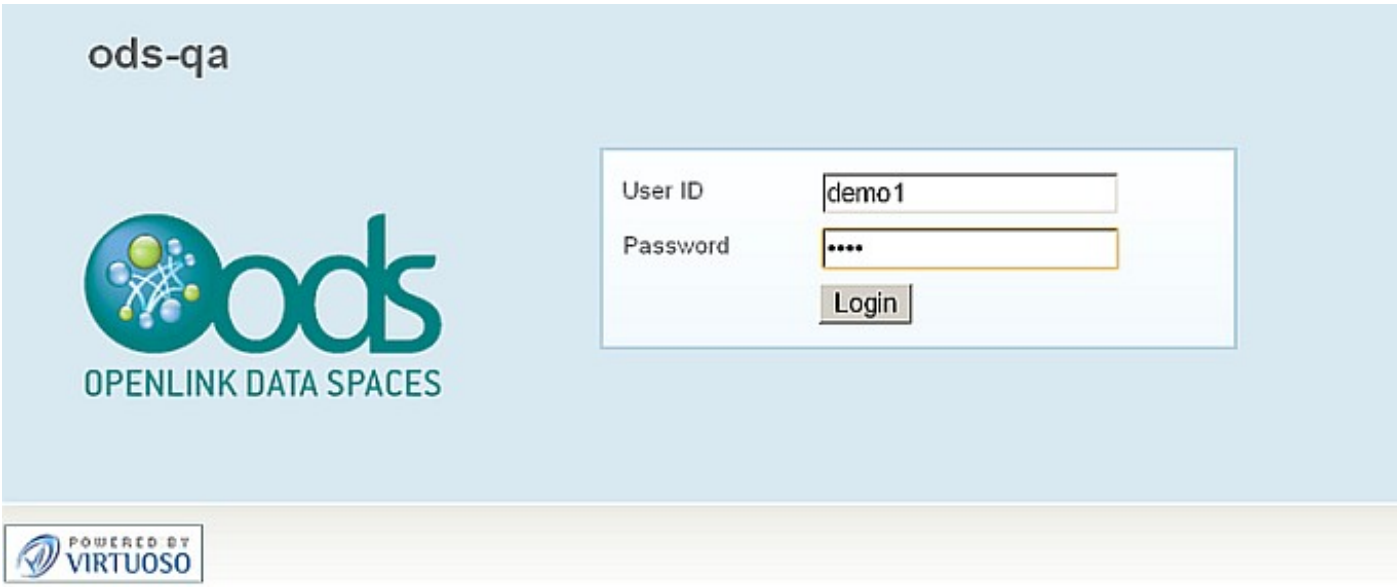
11. Click the "OAuth keys" link:

Figure 16.14. SPARQL OAuth Endpoint



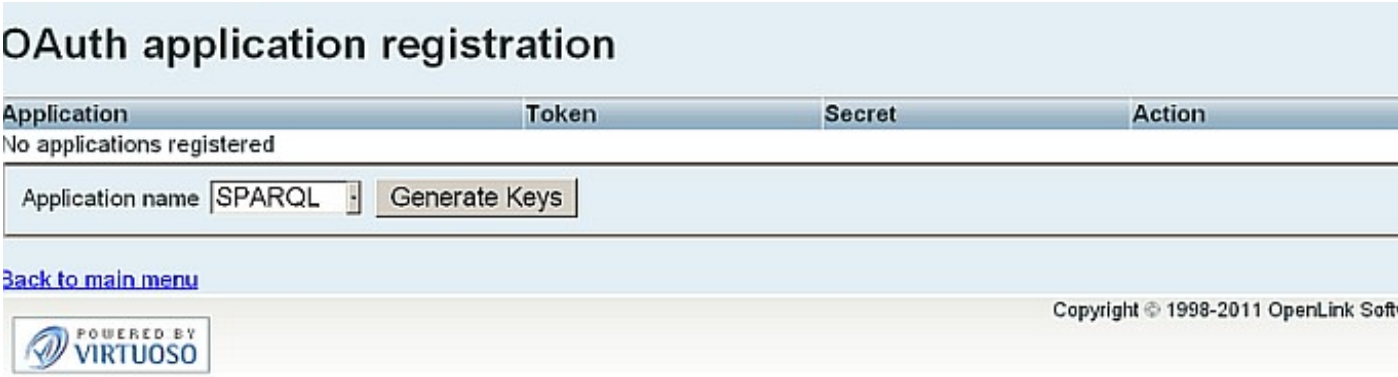
12. Log in as user demo1:

Figure 16.15. SPARQL OAuth Endpoint



13. The OAuth application registration form will be shown.

Figure 16.16. SPARQL OAuth Endpoint



14. Select SPARQL from the "Application name" list, and click the "Generate Keys" button.
15. A Consumer Key for SPARQL will be generated:

```
90baa79108b1d972525bacc76c0279c02d6421e8
```

Figure 16.17. SPARQL OAuth Endpoint

16. Click the "Back to main menu" link.
17. Click the "Protected SPARQL Endpoint" link.
18. The OpenLink Virtuoso SPARQL Query form will be displayed.

Figure 16.18. SPARQL OAuth Endpoint

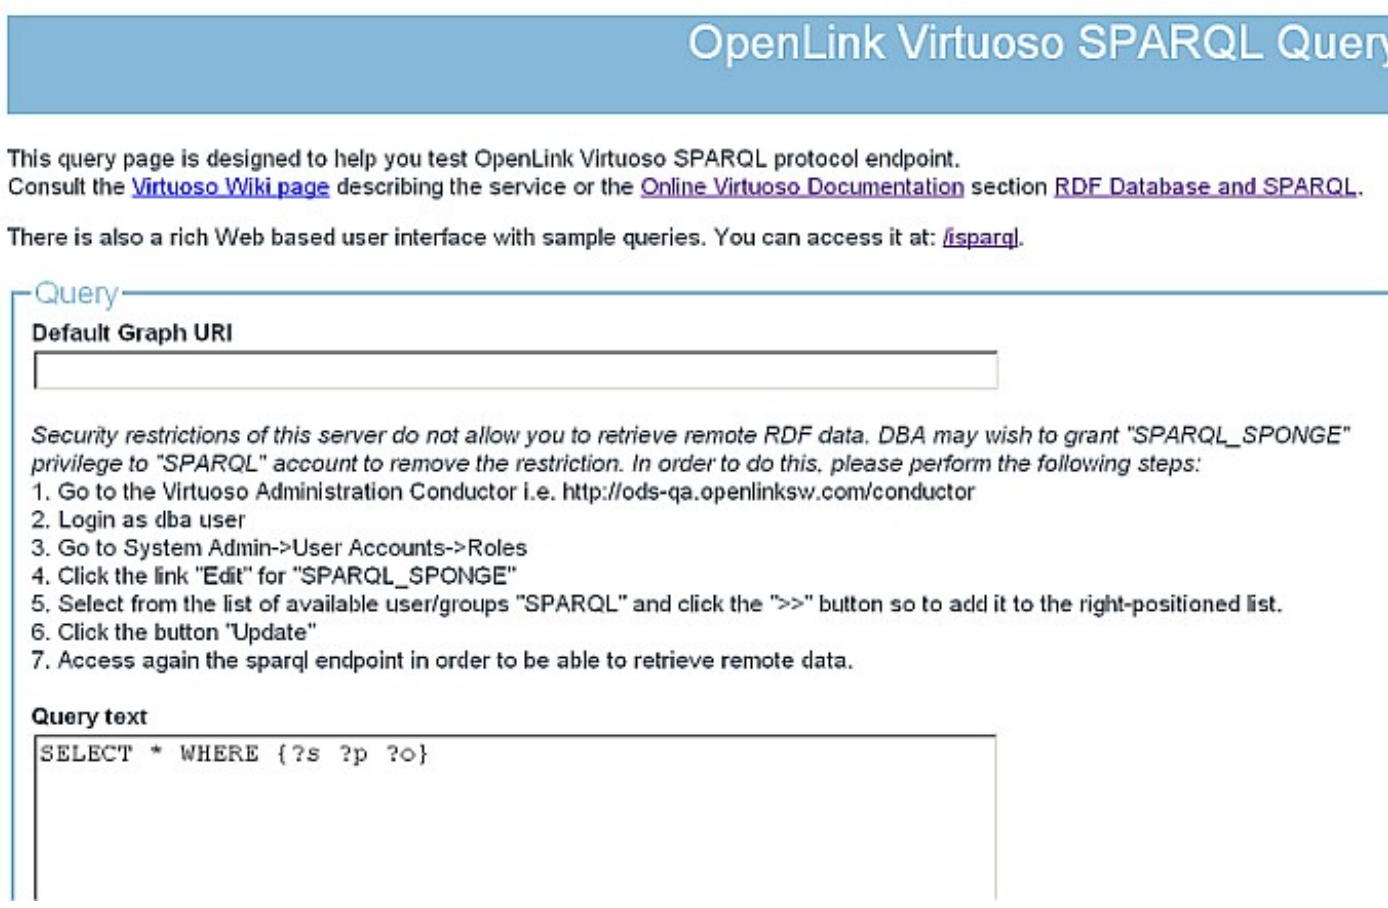


Figure 16.19. SPARQL OAuth Endpoint

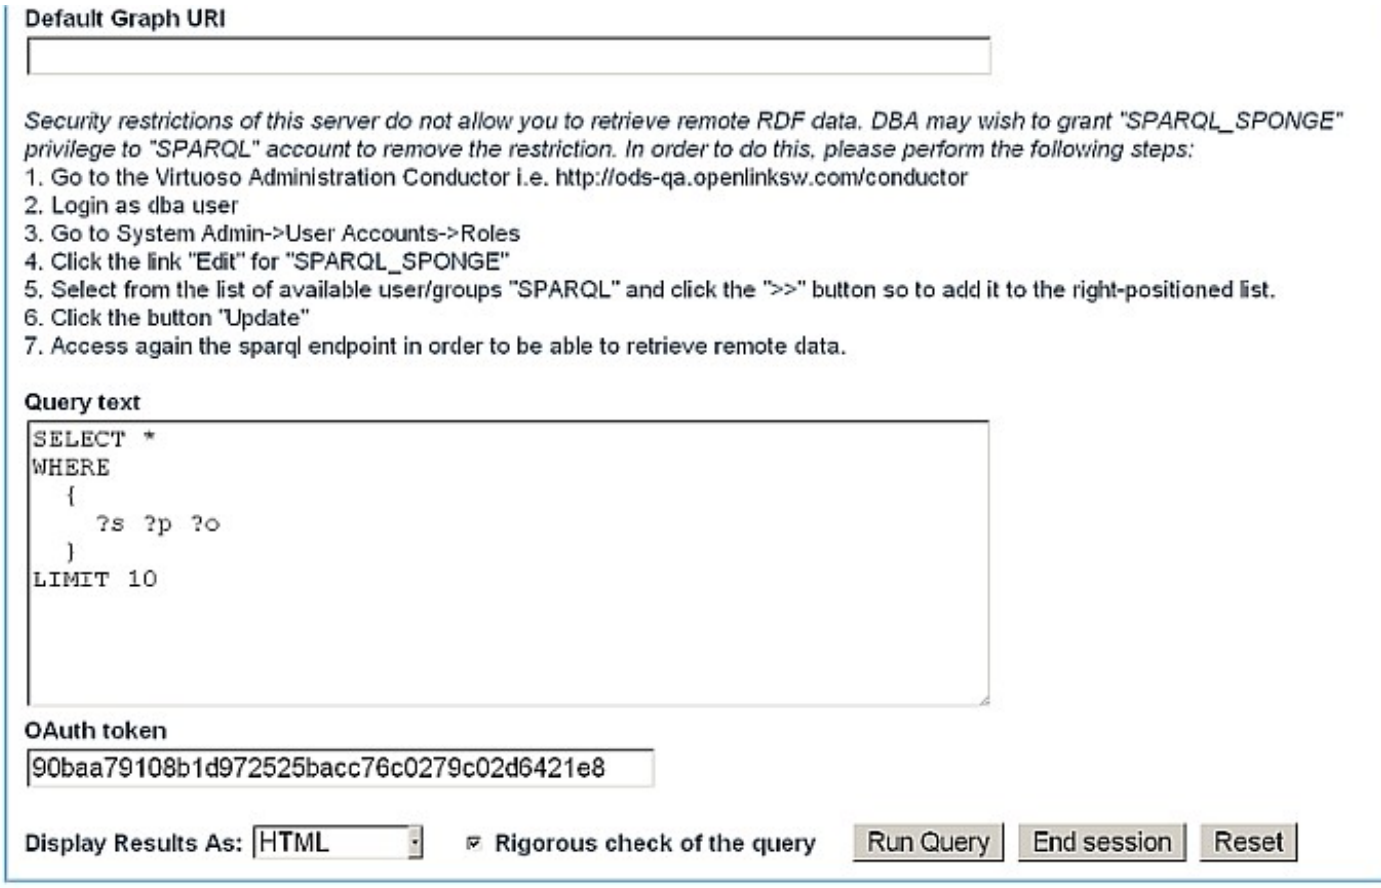
19. Enter a simple query, for ex:

```
SELECT *
WHERE
  {
    ?s ?p ?o
  }
LIMIT 10
```

20. Enter the value from below for the "OAuth token":

```
90baa79108b1d972525bacc76c0279c02d6421e8
```

Figure 16.20. SPARQL OAuth Endpoint

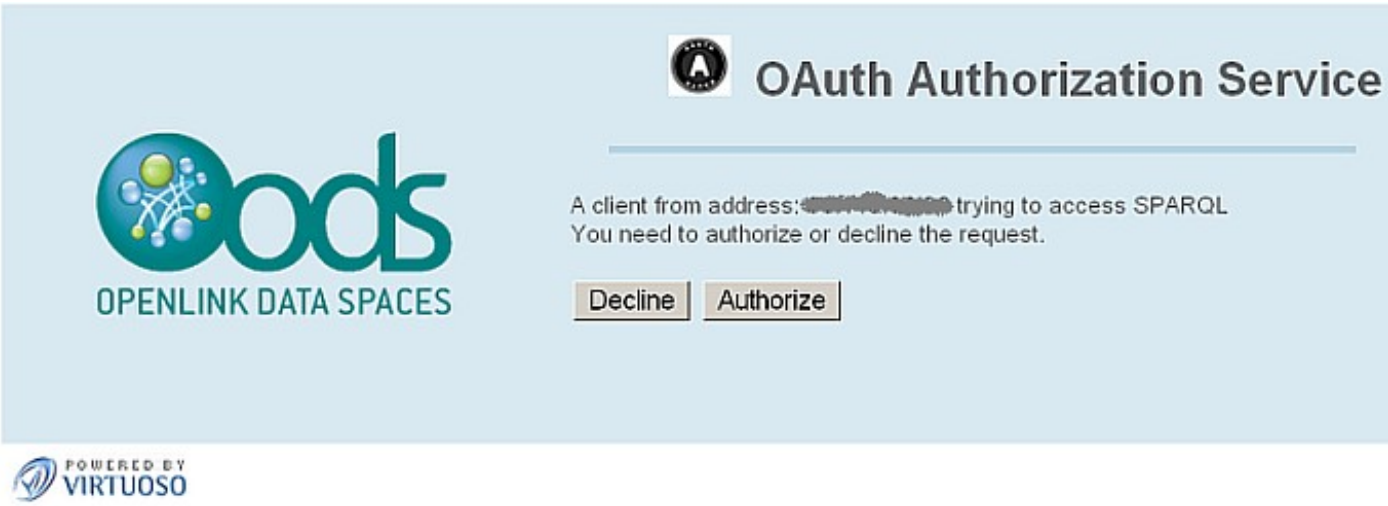


21. Click the "Run Query" button.
22. In the OAuth Authorization Service form enter the password for user demo1 and click the "Login" button.

Figure 16.21. SPARQL OAuth Endpoint

23. Next you should authorize the request:

Figure 16.22. SPARQL OAuth Endpoint



24. On successful authentication and authorization, the query results should be shown:

Figure 16.23. SPARQL OAuth Endpoint

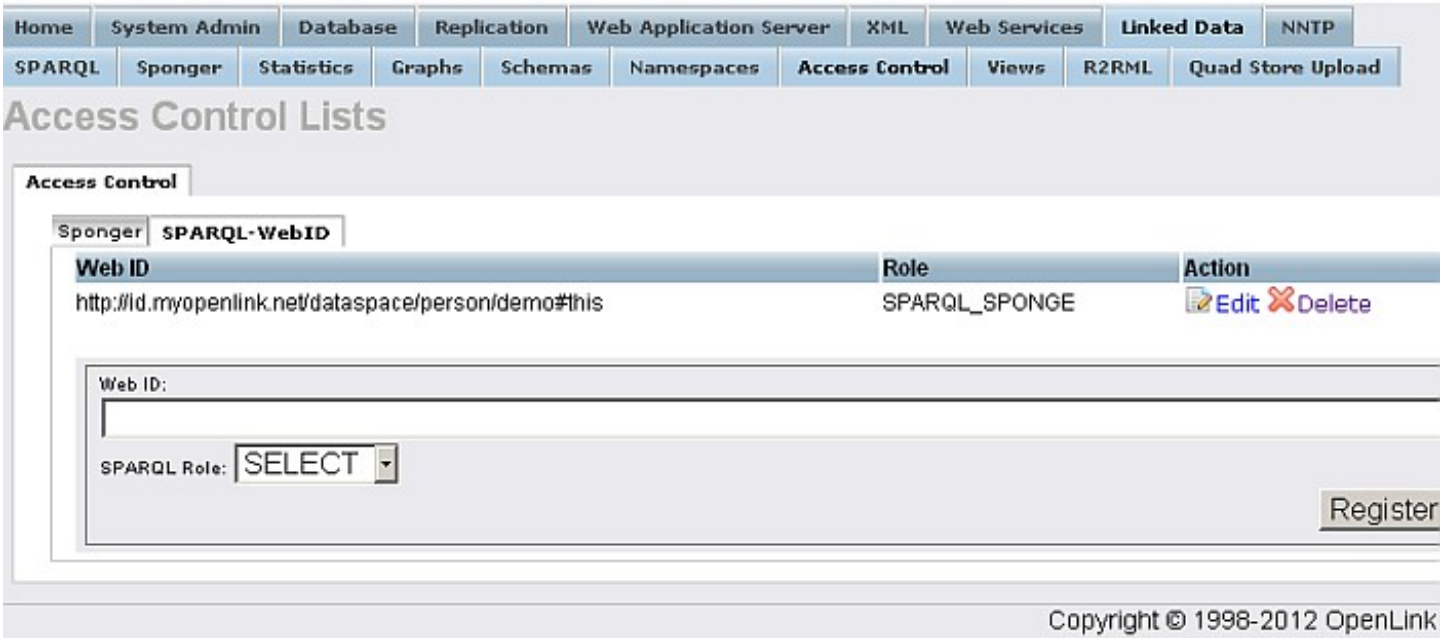
WebID Protocol ACLs

WebID Protocol is an implementation of a conceptual authentication and authorization protocol that links a Web ID to a public key, to create a global decentralized/distributed, and open yet secure authentication system that functions with existing browsers.

To use WebID Protocol, download and install the conductor_dav.vad VAD package. Once installed, to access the WebID Protocol ACLs UI, go to URL http://cname:port/conductor -> Linked Data -> Access Controls -> SPARQL-WebID .

Figure 16.24. WebID



Configuring WebID Protocol ACLs is with a WebID Protocol certificate and a Web ID allows secure SPARQL queries to be performed against a Virtuoso SPARQL-WebID endpoint and viewing of the query results. The SPARQL-WebID endpoint URL is of the form https://cname:port/sparql-webid

Note: SPARQL-SSL is alias of SPARQL-WebID.

See sample example how to configure a sample WebID Protocol ACL are outlined below:

WebID Protocol ODBC Login

Creating and Using a SPARQL-WebID based Endpoint

The following section describes the basic steps for setting up an SSL protected and WebID based SPARQL Endpoint (SPARQL-WebID). The guide also covers the use of Virtuoso PL functions and the Virtuoso Conductor for SPARQL endpoint creation and configuration. It also covers the use of cURL for exercising the newly generated SPARQL-SSL endpoint. Note: SPARQL-SSL is alias of SPARQL-WebID.

1. Setup the CA issuer and https listener
2. To create the /sparql-webid endpoint, install the policy_manager.vad manage or manually define the /sparql-webid endpoint on an HTTPS based listener (HTTPS service endpoint), for example using Virtuoso PL:

```
DB.DBA.VHOST_DEFINE (
         lhost=>'127.0.0.1:443',
         vhost=>'localhost',
         lpath=>'/sparql-webid',
         ppath=>'/!sparql/',
         is_dav=>1,
         auth_fn=>'DB.DBA.FOAF_SSL_AUTH',
         vsp_user=>'dba',
         ses_vars=>0,
         auth_opts=>vector ( 'https_cert',
                             'db:https_key_localhost',
                             'https_key',
                             'db:https_key_localhost',
                             'https_verify',
                             3,
                             'https_cv_depth',
                             10 ),
         opts=>vector ('noinherit', 1),
         is_default_host=>0
);
```

3. Setup the SPARQL-WebID endpoint and define ACLs using the Virtuoso Conductor
4. Export your private key and its associated WebID based X.509 certificate from your Firefox browser or System's Key Manager into PEM (PKCS12) file

    a. If using Firefox use the menu path: Advanced -> View Certificates, then click Backup for your certificate with name "mykey".
    b. The file "mykey.p12" will be created. To disable password protection so that you can use this file in non-interactive mode (e.g. with cURL and other HTTP clients) execute:

```
openssl pkcs12 -in mykey.p12 -out mykey.pem -nodes
```

5. Test the SPARQL-WebID endpoint with cURL: (listening on default HTTPS 443 port):

    - Note: In this example we use the "-k / --insecure" option with cURL since we are going to be using self-signed X.509 certificates signed by self-signed root CA.

```
curl -k -E mykey.pem "https://example.com/sparql-webid?query=select+*+where+\{+%3Fx+%3Fy+%

```

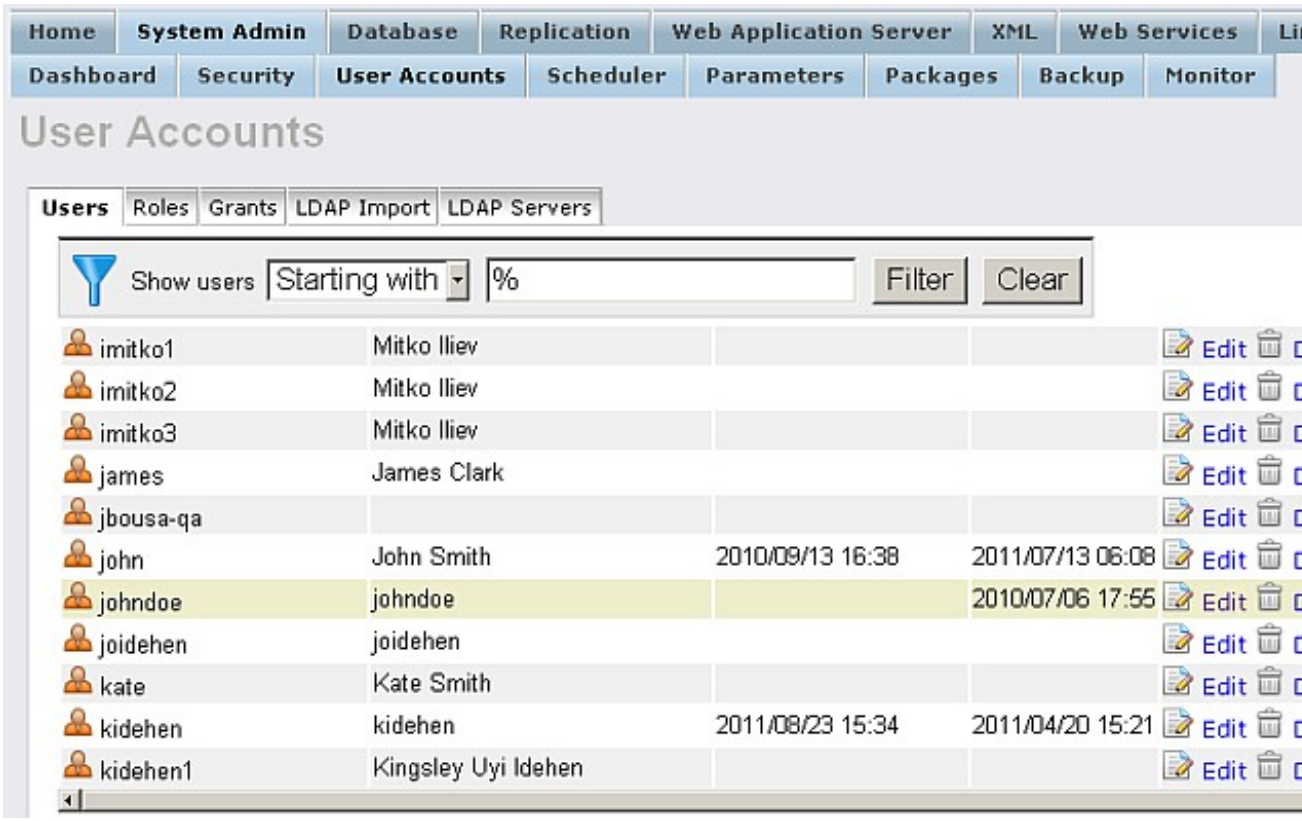
6. Import your key it via Conductor UI:

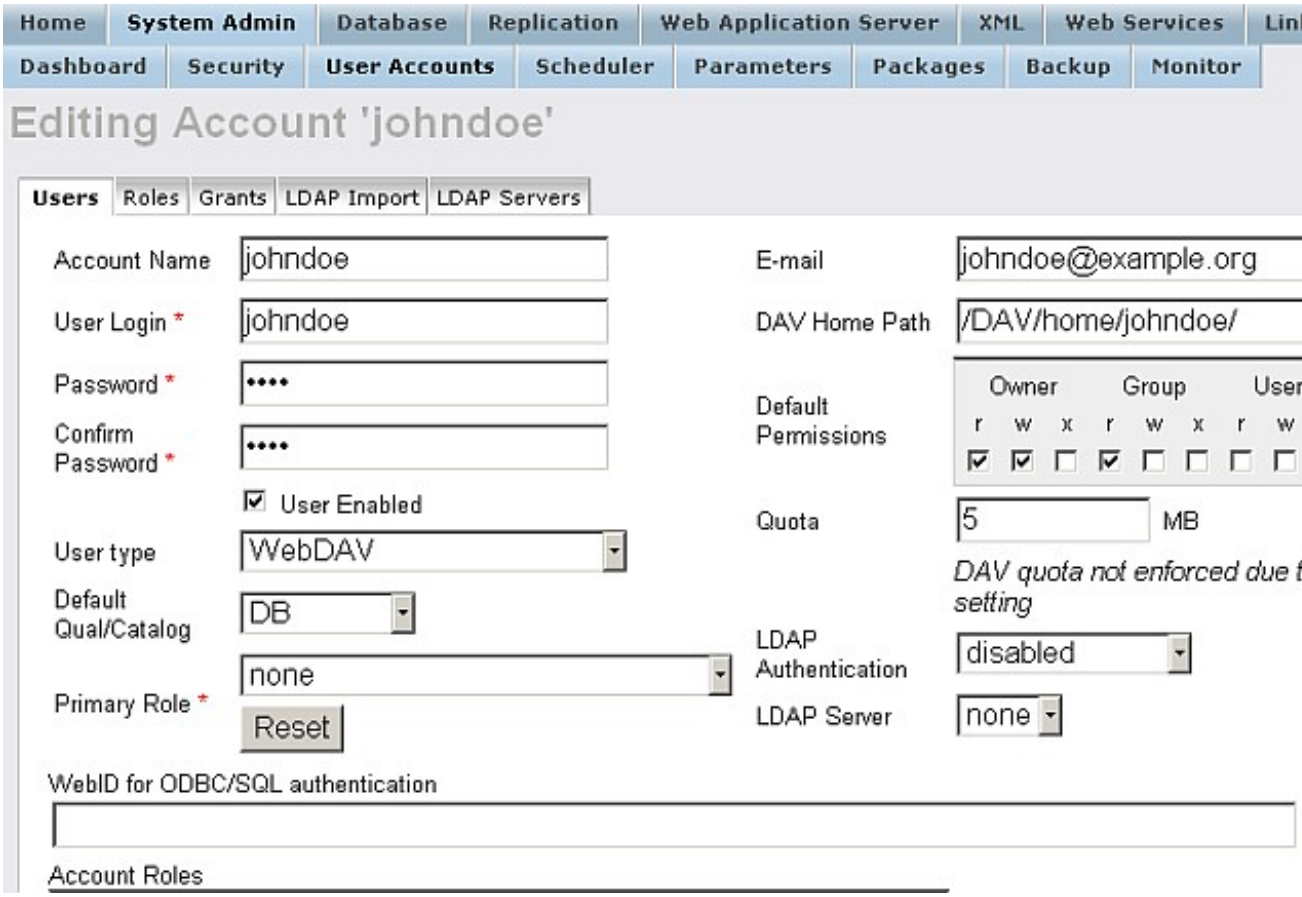
    a. Go to Conductor -> System Admin->User Accounts

Figure 16.25. Import key it via Conductor UI



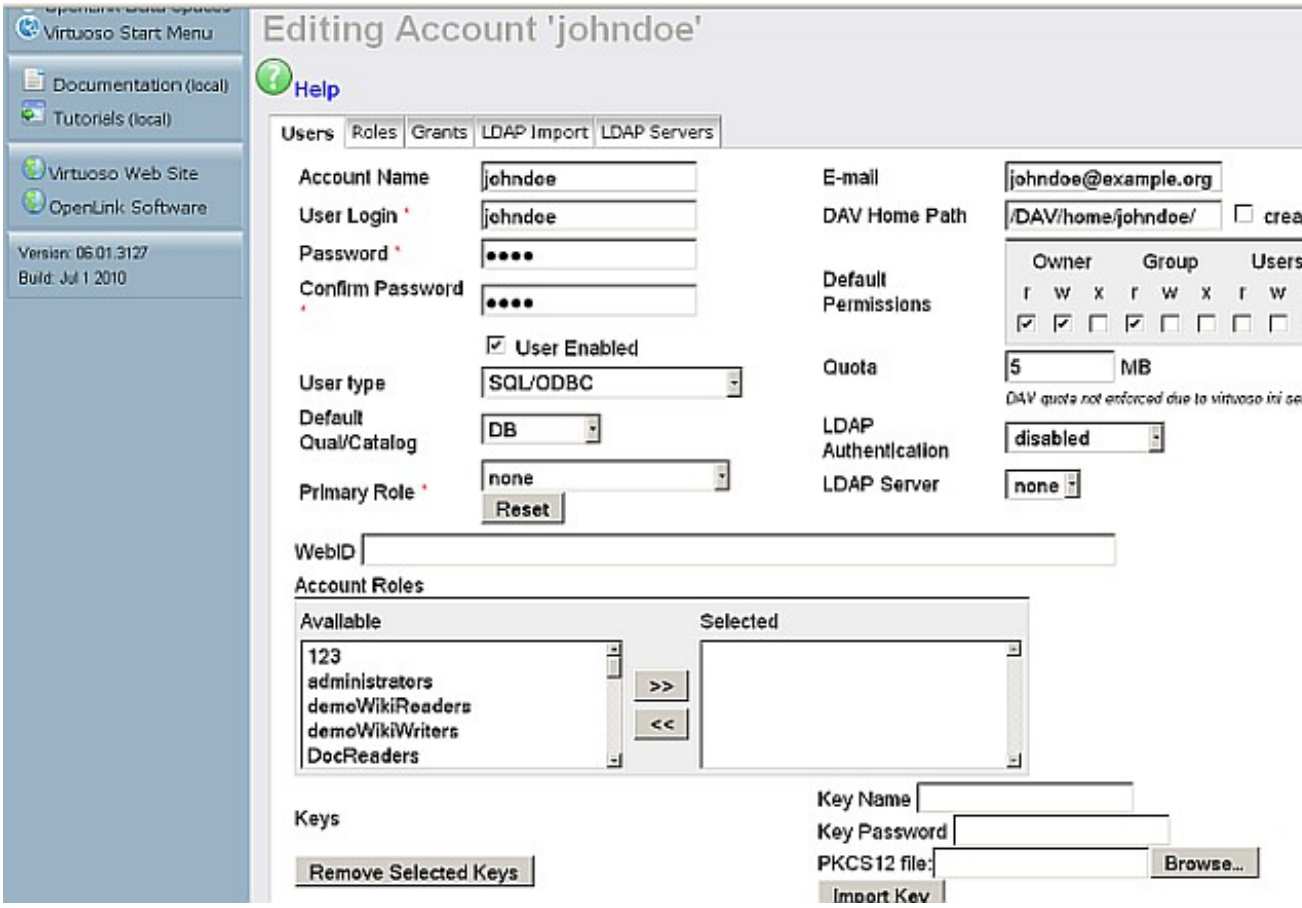
b. Click "Edit" for your user

Figure 16.26. Import key it via Conductor UI



c. Change "User type" to: SQL/ODBC and WebDAV

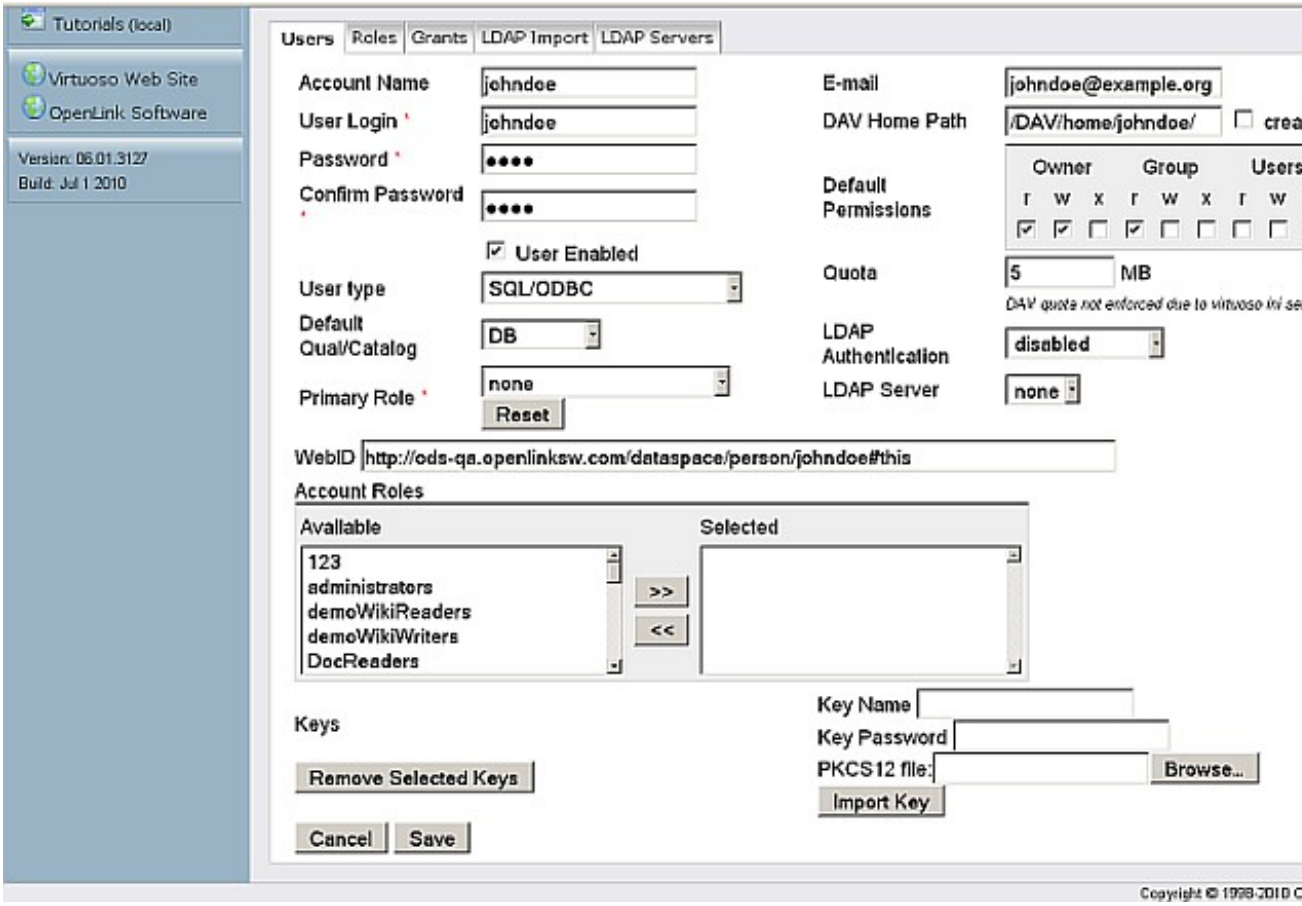
Figure 16.27. Import key it via Conductor UI



d. Enter your ODS user WebID:

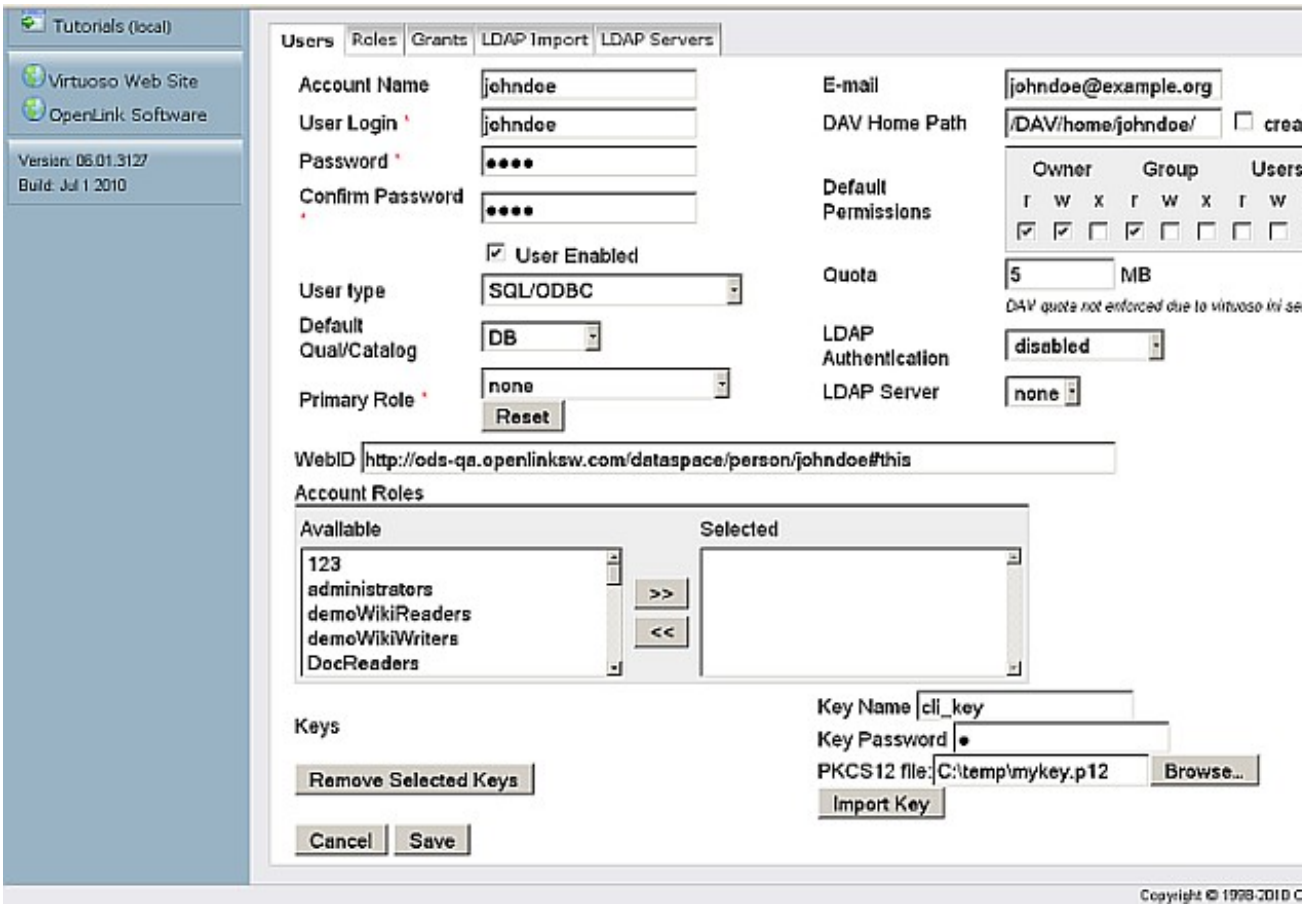
```
http://cname:port/dataspace/person/username#this
```

Figure 16.28. Import key it via Conductor UI



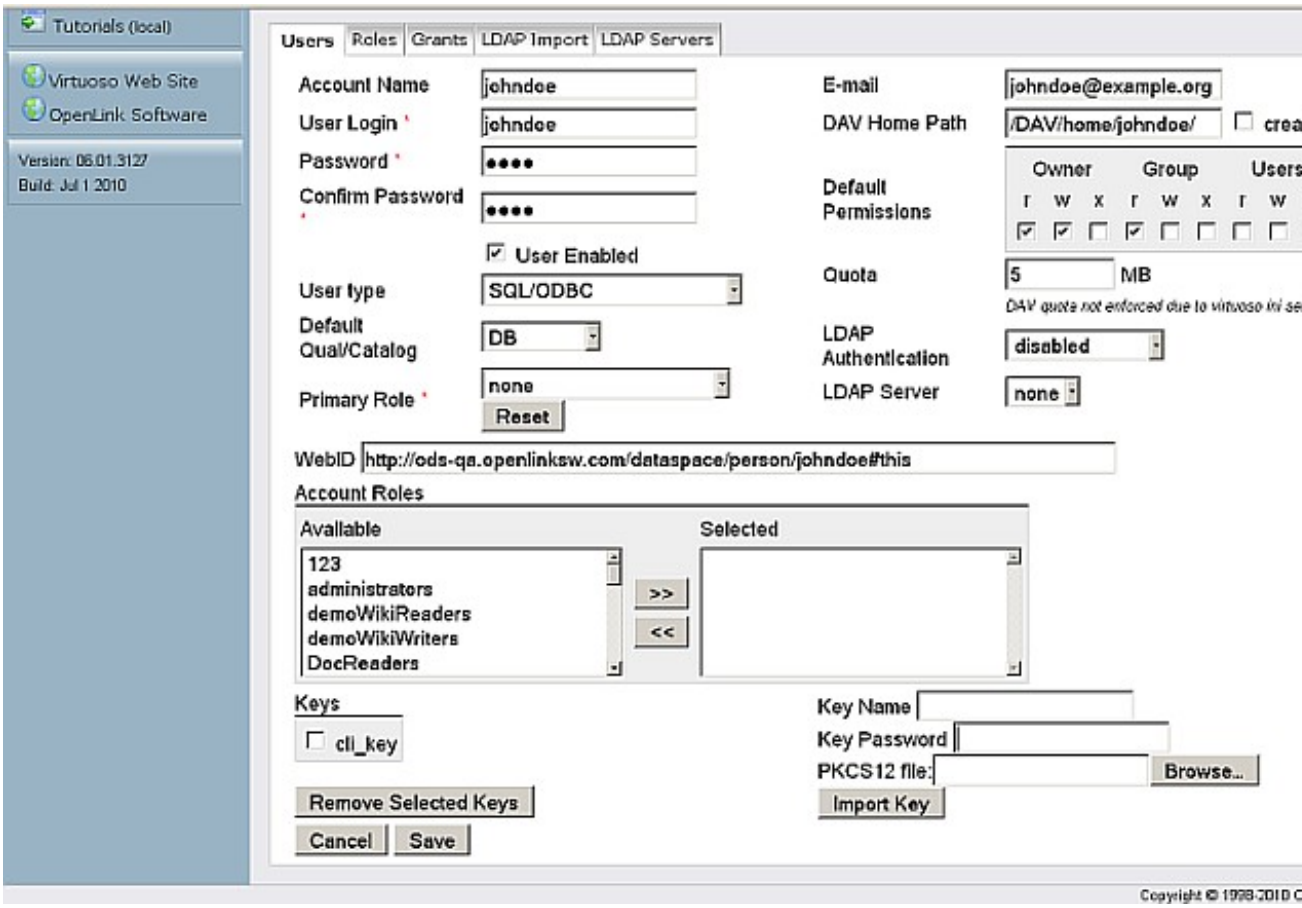
e. Click "Save"
f. Click again "Edit" for your user
g. In "PKCS12 file:" click the Browse" button and select your key.
h. Enter a local Key Name, for e.g., "cli_key"
i. Enter key password

Figure 16.29. Import key it via Conductor UI



j. Click "Import Key"
k. As result the key will be stored with name for ex. cli_key

Figure 16.30. Import key it via Conductor UI



l. Click "Save"

7. Test the SPARQL-WebID endpoint with http_client (listening on default HTTPS 443 port):

a. Log in at Virtuos ISQL with your user credentials:

```
C:\>isql localhost:1111 johndoe****
Connected to OpenLink Virtuoso
Driver: 06.01.3127 OpenLink Virtuoso ODBC Driver
OpenLink Interactive SQL (Virtuoso), version 0.9849b.
Type HELP; for help and EXIT; to exit.
SQL>
```

b. Execute:

```
SQL>select http_client ('https://example.com/sparql-webid?query=select+*+where+{+%3Fx+%3Fy+
b:cli_key', insecure=>1);
callret
VARCHAR

Demo Example Using HTTP client to perform WebID Protocol connection.

Disable Default SPARQL Endpoint

Using iSQL:

1. To disable /sparql, execute:

```
DB.DBA.VHOST_REMOVE (lpath=>'/sparql');
```

2. To add the endpoint again via PL, execute:

```
DB.DBA.VHOST_DEFINE (lpath=>'/sparql/', ppath => '/!sparql/', is_dav => 1, vsp_user => 'dba', opts
```

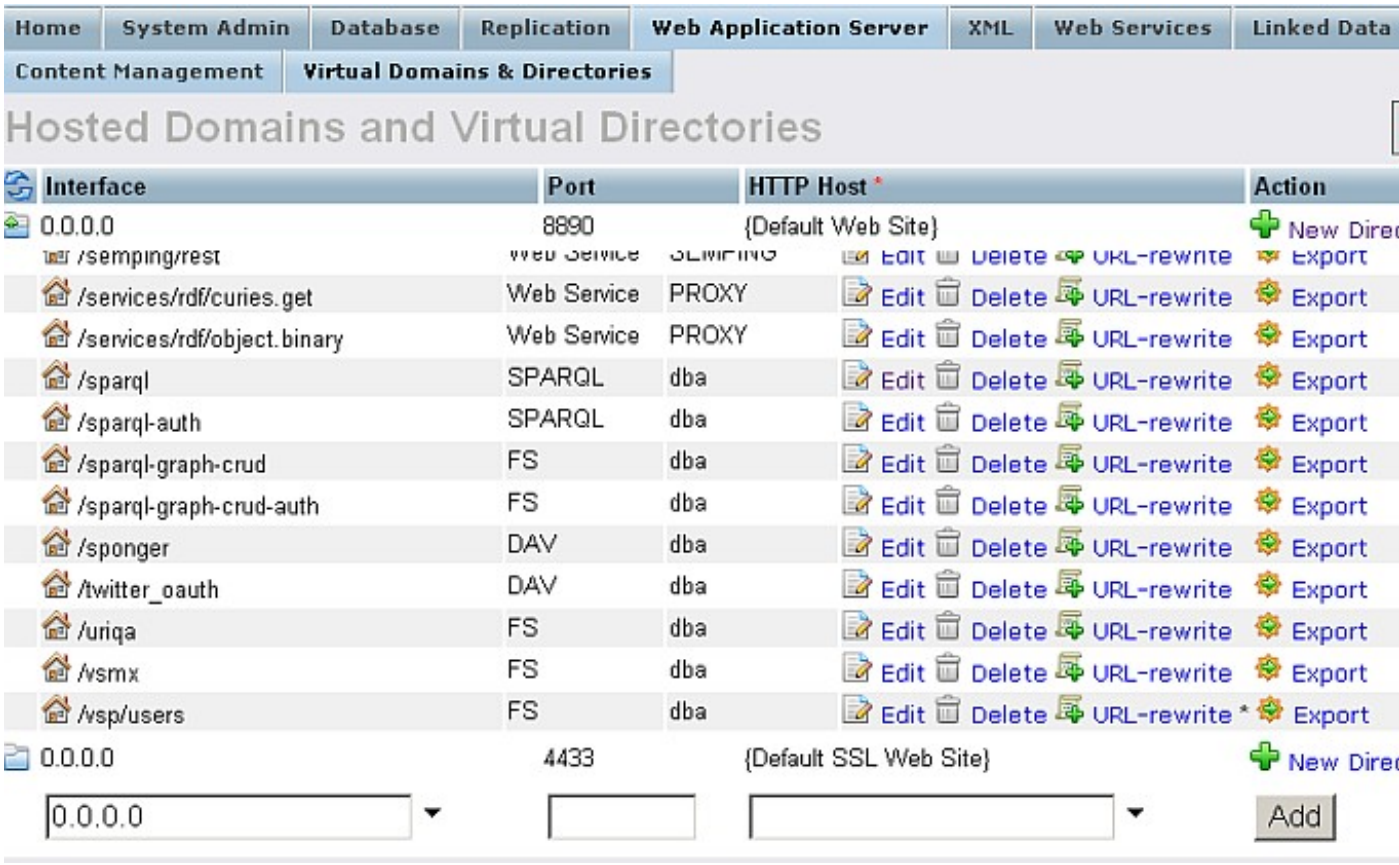
Using Conductor UI:

1. Go to http://cname:port/conductor .
2. Enter user dba credentials.
3. Go to "Web Application Server" -> "Virtual Domains & Directories".

Figure 16.31. Disable SPARQL Endpoint

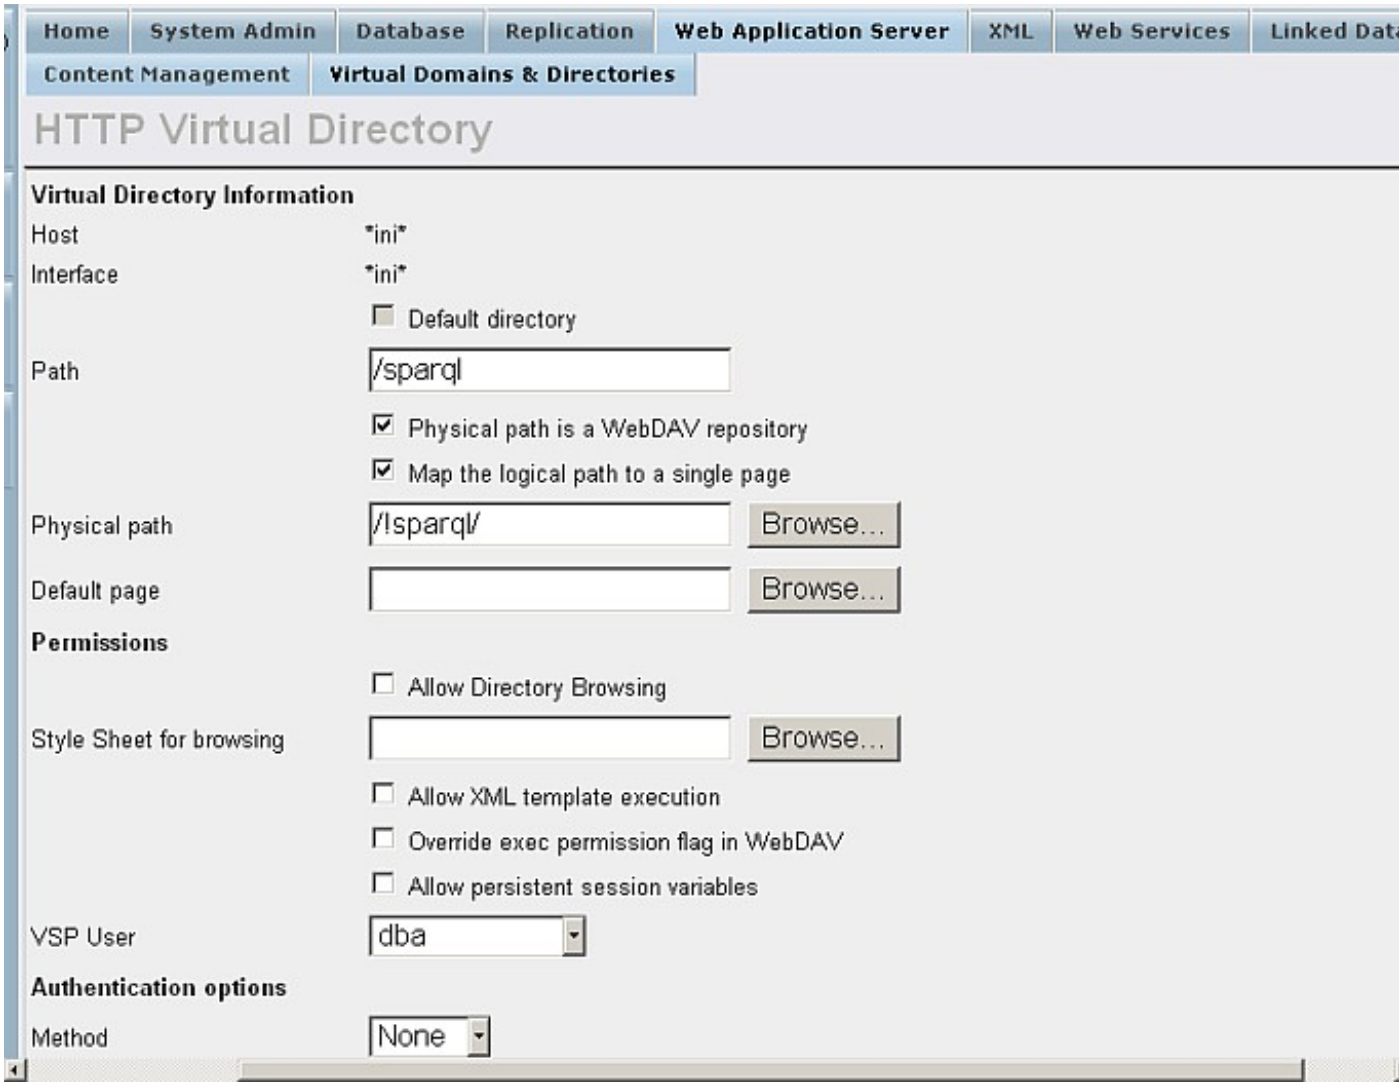
4. Find the logical path "/sparql".

Figure 16.32. Disable SPARQL Endpoint



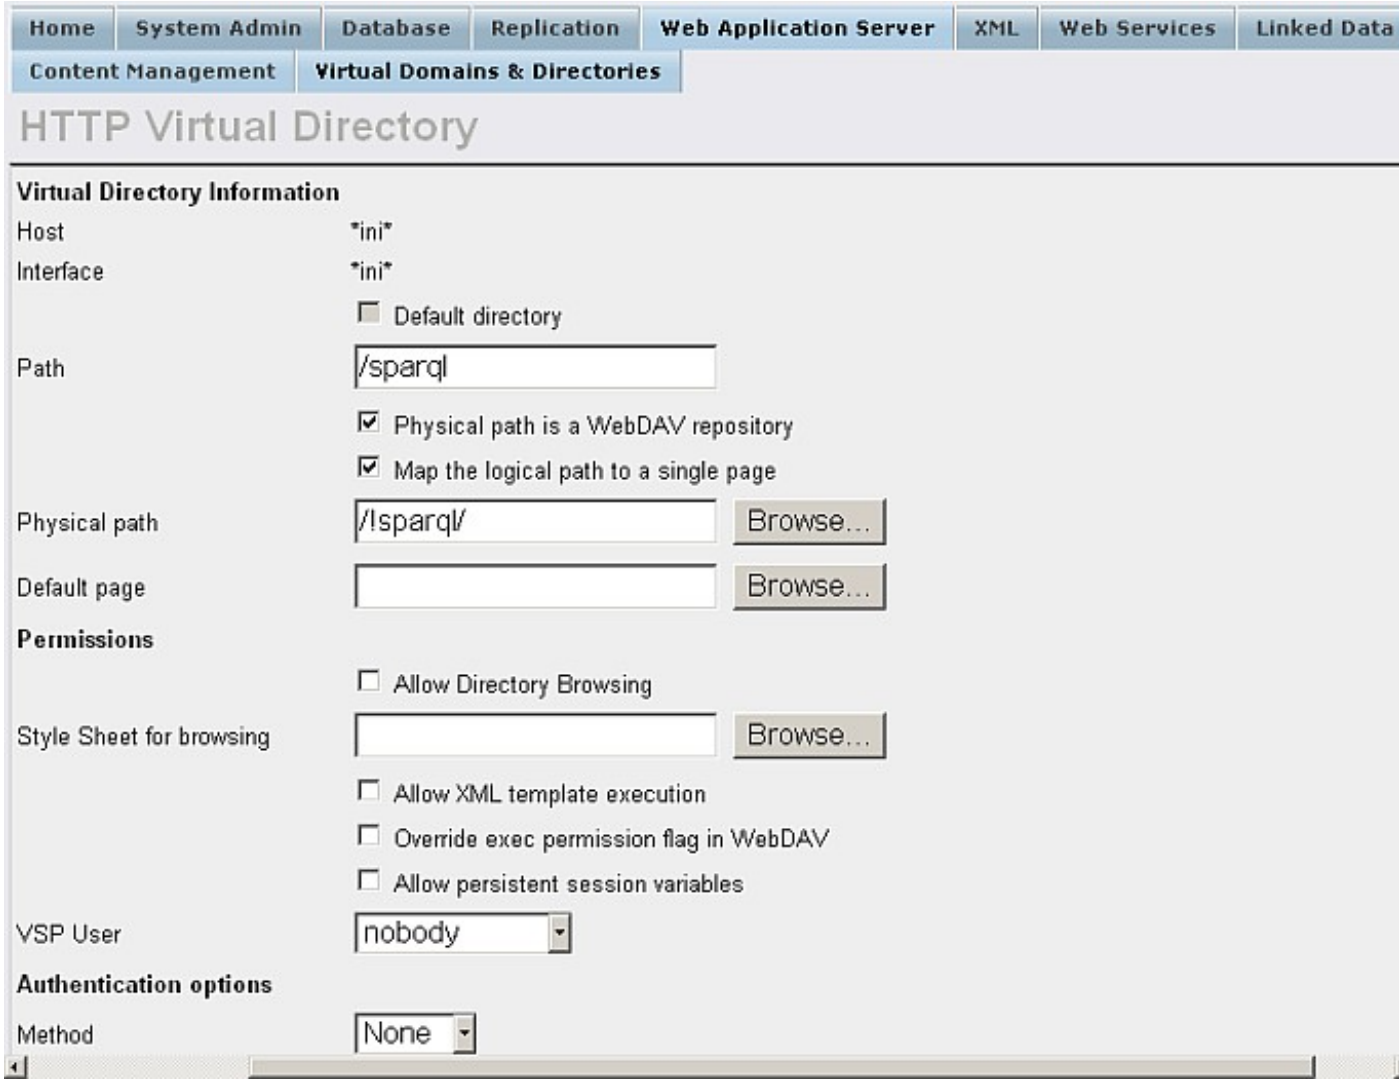
5. Click "Edit" from the "Action" column.

Figure 16.33. Disable SPARQL Endpoint



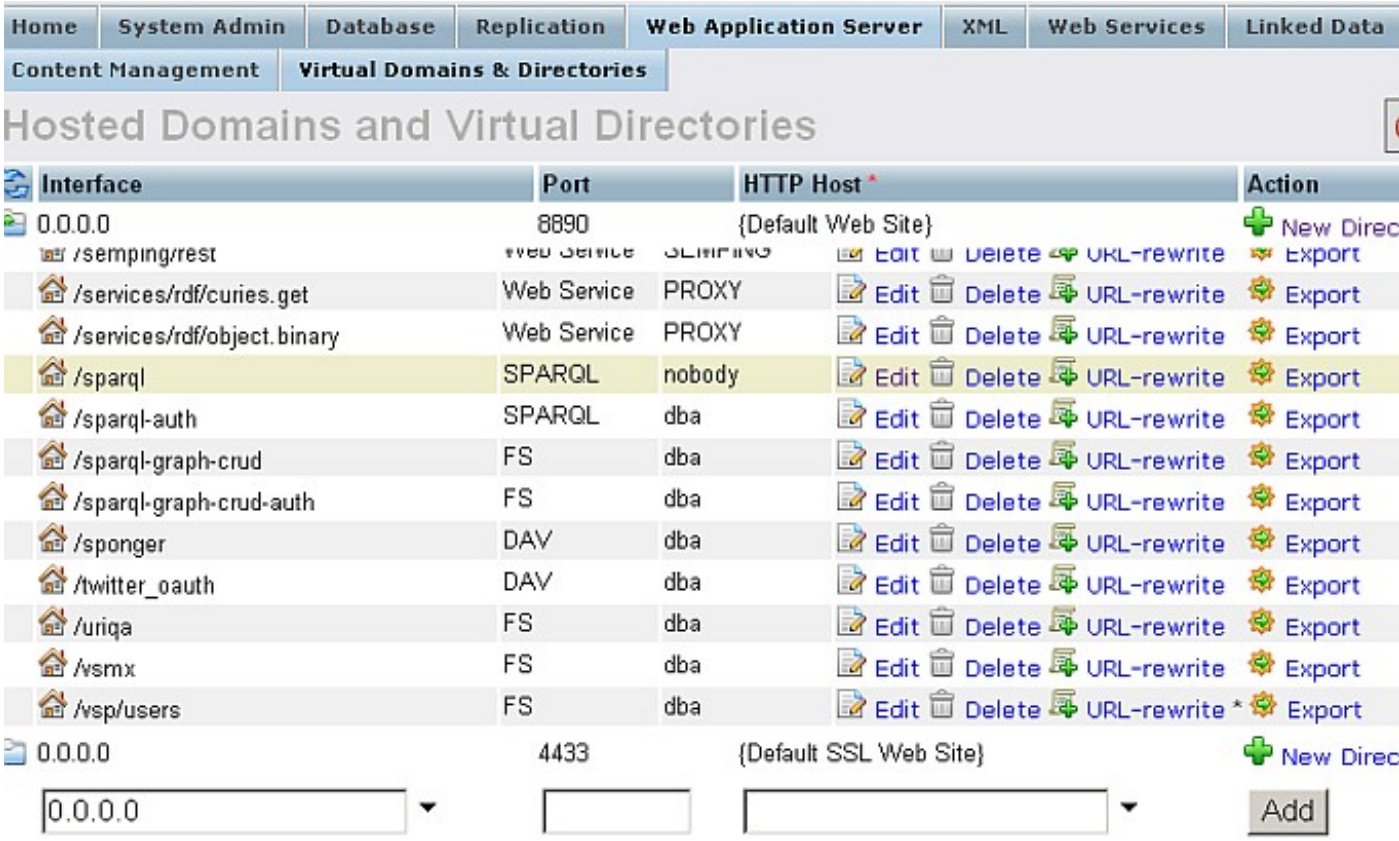
6. Change "VSP User" to "nobody".

Figure 16.34. Disable SPARQL Endpoint



7. Click "Save Changes".
8. As result the SPARQL Endpoint should be shown as disabled:

Figure 16.35. Disable SPARQL Endpoint



Request Methods

Table 16.6. Methods List

Method	Supported?	Notes
GET	Yes	Short queries are sent in GET mode
POST	Yes	Queries longer than 1900 bytes are POST-ed.
DELETE	No	
PUT	No	

Functions

The SPARQL client can be invoked by three similar functions:

Table 16.7. Functions List

Function	Notes
DB.DBA.SPARQL_REXEC	Behaves like DBA.SPARQL_EVAL, but executes the query on the specified server. The procedure does not return anything. Instead, it creates a result set.
DB.DBA.SPARQL_REXEC_TO_ARRAY	Behaves like DBA.SPARQL_EXEC_TO_ARRAY (), but executes the query on the specified server. The function return a vector of rows, where every row is represented by a vector of field values.
DB.DBA.SPARQL_REXEC_WITH_META	Has no local 'SPARQL_EVAL' analog. It produces an array of result rows together with an array of result set metadata in the same format as produced by the exec () function. This function can be used when the result should be passed later to exec_result_names () and exec_result () built-in functions. To process a local query in similar style, an application can use the SQL built-in function exec () - a SPARQL query (with the 'SPARQL' keyword in front) can be passed to exec () instead of a plain SQL SELECT statement.

```
create procedure DB.DBA.SPARQL_REXEC (
    in service varchar, in query varchar, in dflt_graph varchar, in named_graphs any,
    in req_hdr any, in maxrows integer, in bnode_dict any );

create function DB.DBA.SPARQL_REXEC_TO_ARRAY (
    in service varchar, in query varchar, in dflt_graph varchar, in named_graphs any,
    in req_hdr any, in maxrows integer, in bnode_dict any )
    returns any;

create procedure DB.DBA.SPARQL_REXEC_WITH_META (
    in service varchar, in query varchar, in dflt_graph varchar, in named_graphs any,
    in req_hdr any, in maxrows integer, in bnode_dict any,
    out metadata any,  -- metadata like exec () returns.
    out resultset any) -- results as 'long valmode' values.
```

Examples

Virtuoso's SPARQL demo offers a live demonstration of Virtuoso's implementation of the DAWG's SPARQL test-suite , a collection of SPARQL query language use cases that enable interactive and simplified testing of a triple store implementation. If you have installed the SPARQL Demo VAD locally, it can be found at a URL similar to 'http://example.com:8080/sparql_demo/', the exact form will depend on your local configuration. Alternatively, a live version of the documentation is available at Virtuoso Demo Server .

Example SPARQL query issued via curl

```
curl -F "query=SELECT DISTINCT ?p FROM <http://demo.openlinksw.com/DAV/home/demo/rdf_sink/> WHERE {?s ?p
```

The result should be:

```
<?xml version="1.0" ?>
<sparql xmlns="http://www.w3.org/2005/sparql-results#" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instan
 <head>
  <variable name="p"/>
 </head>
 <results distinct="false" ordered="true">
  <result>
   <binding name="p"><uri>http://www.w3.org/1999/02/22-rdf-syntax-ns#type</uri></binding>
  </result>
  <result>
   <binding name="p"><uri>http://xmlns.com/foaf/0.1/nick</uri></binding>
  </result>
  <result>
   <binding name="p"><uri>http://xmlns.com/foaf/0.1/name</uri></binding>
  </result>
  <result>
   <binding name="p"><uri>http://xmlns.com/foaf/0.1/homepage</uri></binding>
  </result>
  <result>
   <binding name="p"><uri>http://xmlns.com/foaf/0.1/knows</uri></binding>
  </result>
  <result>
   <binding name="p"><uri>http://xmlns.com/foaf/0.1/workplaceHomepage</uri></binding>
  </result>
  <result>
   <binding name="p"><uri>http://xmlns.com/foaf/0.1/mbox</uri></binding>
  </result>
 </results>
</sparql>
```

Other Examples of SPARQL query issued via curl

Further example SPARQL queries:

```
curl -F "query=SELECT DISTINCT ?Concept FROM <http://dbpedia.org> WHERE {?s a ?Concept} LIMIT 10" http://

curl -F "query=SELECT DISTINCT ?Concept FROM <http://example.com/dataspace/person/kidehen> WHERE {?s a ?C

curl -F "query=SELECT DISTINCT ?Concept FROM <http://data.openlinksw.com/oplweb/product_family/virtuoso>
```

```
curl -F "query=SELECT DISTINCT ?Concept FROM <http://openlinksw.com/dataspace/organization/openlink> WHER
```

Example with curl and SPARQL-WebID endpoint

```
$ curl -H "Accept: text/rdf+n3"  --cert test.pem -k https://demo.openlinksw.com/dataspace/person/demo
Enter PEM pass phrase: *****

```

```
</table>
```

Example with CONSTRUCT

Go to the sparql endpoint UI: i.e. go to http://host:port/sparql

For the Default Graph URI enter: http://www.w3.org/2001/sw/DataAccess/proto-tests/data/construct/simple-data.rdf

Select "Retrieve remote RDF data for all missing source graphs".

For the query text enter:

```
SELECT * WHERE {?s ?p ?o}
```

Click the "Run Query" button.

The query results, shown below, are cached locally (network resources being fetched). The remote RDF data is saved in the local RDF quad store as graph http://www.w3.org/2001/sw/DataAccess/proto-tests/data/construct/simple-data.rdf

```
s                                       p                                                o
http://www.example/jose/foaf.rdf#jose     http://www.w3.org/1999/02/22-rdf-syntax-ns#type  http://xmlns.c
http://www.example/jose/foaf.rdf#jose     http://xmlns.com/foaf/0.1/nick                   Jo
http://www.example/jose/foaf.rdf#jose     http://xmlns.com/foaf/0.1/name                   Jose Jimen~ez
http://www.example/jose/foaf.rdf#jose     http://xmlns.com/foaf/0.1/knows                  http://www.exa
http://www.example/jose/foaf.rdf#jose     http://xmlns.com/foaf/0.1/homepage               http://www.exa
http://www.example/jose/foaf.rdf#jose     http://xmlns.com/foaf/0.1/workplaceHomepage      http://www.cor
http://www.example/jose/foaf.rdf#kendall  http://xmlns.com/foaf/0.1/knows                  http://www.exa
http://www.example/jose/foaf.rdf#julia    http://www.w3.org/1999/02/22-rdf-syntax-ns#type  http://xmlns.c
http://www.example/jose/foaf.rdf#julia    http://xmlns.com/foaf/0.1/mbox                   mailto:julia@m
http://www.example/jose/foaf.rdf#juan     http://www.w3.org/1999/02/22-rdf-syntax-ns#type  http://xmlns.c
http://www.example/jose/foaf.rdf#juan     http://xmlns.com/foaf/0.1/mbox                   mailto:juan@ma
```

Now let's take the CONSTRUCT query:

```
PREFIX rdf: <http://www.w3.org/1999/02/22-rdf-syntax-ns#>
PREFIX foaf: <http://xmlns.com/foaf/0.1/>
PREFIX myfoaf: <http://www.example/jose/foaf.rdf#>
CONSTRUCT
  { myfoaf:jose foaf:depiction <http://www.example/jose/jose.jpg>.
    myfoaf:jose foaf:schoolHomepage <http://www.edu.example/>.
    ?s ?p ?o.
  }
FROM <http://www.w3.org/2001/sw/DataAccess/proto-tests/data/construct/simple-data.rdf>
WHERE
  {
    ?s ?p ?o. myfoaf:jose foaf:nick "Jo".
    FILTER ( ! (?s = myfoaf:kendall && ?p = foaf:knows && ?o = myfoaf:edd )
    && ! ( ?s = myfoaf:julia && ?p = foaf:mbox && ?o = <mailto:julia@mail.example> )
    && ! ( ?s = myfoaf:julia && ?p = rdf:type && ?o = foaf:Person))
  }
```

From an HTTP client, issue the GET command with the above query added as a URL-encoded parameter value:

```
GET -e -s http://host:port/sparql/?query=PREFIX+rdf%3A+%3Chttp%3A%2F%2Fwww.w3.org%2F1999%2F02%2F22-rdf-sy
```

The request response will be similar to:

```
200 OK
Connection: close
Date: Fri, 28 Dec 2007 10:06:14 GMT
Accept-Ranges: bytes
Server: Virtuoso/05.00.3023 (Win32) i686-generic-win-32  VDB
Content-Length: 2073
Content-Type: application/rdf+xml; charset=UTF-8
Client-Date: Fri, 28 Dec 2007 10:06:14 GMT
Client-Peer: 83.176.40.177:port
Client-Response-Num: 1
```

```
<?xml version="1.0" encoding="utf-8" ?>

```

Example with extraction part of literal as variable

The following example shows how to extract a part of a literal as a variable for use in a numeric comparison using SPARQL

Suppose there are the following triples inserted:

```
SQL>SPARQL INSERT INTO GRAPH <http://mygraph.com> {  <:a>
                                                     <:p>
                                                     "123 abc" };
callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://mygraph.com>, 1 triples -- done

1 Rows. -- 30 msec.
SQL>SPARQL INSERT INTO GRAPH <http://mygraph.com> {  <:a>
                                                     <:p>
                                                     "234 abc" };
callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://mygraph.com>, 1 triples -- done

1 Rows. -- 0 msec.
```

In order to extract the numeric part, and then do a numeric (<.>,=), you can use atoi (), atol or atof in the filter:

```
SQL>SPARQL
SELECT *
FROM <http://mygraph.com>
WHERE
  {
    ?s ?p ?o . filter (bif:atoi (?o) > 130)
  };
s         p         o
VARCHAR   VARCHAR   VARCHAR
_____________________________________

:a        :p        234 abc

1 Rows. -- 10 msec.
```

Example how to define rule

See details here how to define rule context that is initialized from the contents of a given graph.

Implementation Notes

This service has been implemented using Virtuoso Server .

Virtuoso 'Semantic Bank' End Point

What is Piggy Bank?

Piggy Bank is an extension to the Firefox Web browser that turns it into a Semantic Web browser, letting you make use of existing information on the Web in more useful and flexible ways not offered by the original Web sites.

What is Semantic Bank?

Semantic Bank is the server companion of Piggy Bank that lets you persist, share and publish data collected by individuals, groups or communities. Here is a screen shot of one in action:

What can I do with this?

A Semantic Bank allows you to:

- Persist your information remotely on a server - This is useful, for example, if you want to share data between two of your computers or to avoid losing it due to mistakes or failure.
- Share information with other people - The ability to tag resources creates a powerful serendipitous categorization (as proven by things like del.icio.us or Flickr).
- Lets you publish your information - Both in the "pure" RDF form (for those who know how to make use of it) or to regular web pages, with the usual Longwell faceted browsing view of it

How can I help?

Semantic Bank is Open Source software and built around the spirit of open participation and collaboration.

There are several ways you can help:

- Install a Semantic Bank and let us know about it, so that we can update the list of available Semantic Banks.
- Subscribe to our mailing lists to show your interest and give us feedback
- Report problems and ask for new features through our issue tracking system.
- Send us patches or fixes to the code

Licensing and Legal Issues

Semantic Bank is open source software and is licensed under the BSD license.

Note , however, that this software ships with libraries that are not released under the same license; that we interpret their licensing terms to be compatible with ours and that we are redistributing them unmodified. For more information on the licensing terms of the libraries Semantic Bank depends on, please refer to the source code.

Download location:

"http://simile.mit.edu/dist/semantic-bank/

The Virtuoso Semantic Bank End Point

Before you can publish, you must register with one or more Semantic Banks:

- Invoke the menu command Tools > Piggy Bank > My Semantic Bank Accounts ...
- Click Add... in the Semantic Bank Accounts dialog box.
- In the popup dialog box, type in the URL to the Virtuoso Semantic Bank you want to register with. Example: http://server_name:server_port/bank
- Enter the account of a valid Virtuoso DAV user. (Note: currently we do not use encryption during authentication; do not use your precious password here.)
- Click OK, wait for the account to be registered, and then dismiss the Semantic Bank Accounts dialog box.
- To publish an item, just click the corresponding Publish button (much like how you save the item). To publish all the items being viewed, click the Publish All button.

What is the graph name used by Virtuoso for the triples from PiggyBank?

http://simile.org/piggybank/<piggybank-generated-name>

The piggybank-generated-name is a Virtuoso DAV user ID.

Making Linked Data Views Dereferenceable - Northwind Example

Consider an application that makes some relational data available for SPARQL requests, as described in the first part of the Northwind Linked Data View example . This may be sufficient for some clients but the IRIs of the described subjects are not dereferenceable. This means that external SPARQL processors cannot retrieve that data using the Virtuoso Sponger or the like. It also means that if some external resources refer to the IRI of some Northwind subject and a user browses that resource then he cannot look at the application's data by clicking on the subject link.

To make RDF access complete, applications can do the following:

1. Create a virtual directory
2. Instruct the server how to prepare RDF resources on demand
3. Configure rendering of RDF resources for non-RDF clients (including Web search engines)
4. Make the used ontology available
5. Provide an index or sitemap page to help users who try to browse published data but do not know the proper URLs

The following sequence of operations demonstrates how to implement the listed features without writing any special web pages. All requests (except the application-specific index/sitemap) will be handled by existing web service endpoints.

As a precaution, we erase any URL rewriting rule lists created by this example that may be in the database following a previous run of the script.

```
DB.DBA.URLREWRITE_DROP_RULELIST ('demo_nw_rule_list1', 1)
;
```

Do the same for individual rewrite rules:

```
DB.DBA.URLREWRITE_DROP_RULE ('demo_nw_rule1', 1)
;
DB.DBA.URLREWRITE_DROP_RULE ('demo_nw_rule2', 1)
;
DB.DBA.URLREWRITE_DROP_RULE ('demo_nw_rule3', 1)
;
DB.DBA.URLREWRITE_DROP_RULE ('demo_nw_rule4', 1)
;
```

As a sanity check we ensure that there are no other similarly named rules:

```
SQL>SELECT signal ('WEIRD', sprintf ('Rewrite rule "%s" found', URR_RULE))
FROM DB.DBA.URL_REWRITE_RULE WHERE URR_RULE like 'demo_nw%'
;
```

Next we create URI rewrite rules based on regular expressions by calling `DB.DBA.URLREWRITE_CREATE_REGEX_RULE` , so the same path will be redirected to different places depending on the MIME types the client can accept.

For a given input path, that is a URI identifying a particular Linked Data entity, the rewrite rule below generates an N3 or RDF/XML representation of the entity using a CONSTRUCT query. (Note: In the regular expression identifying the Accept: MIME types this rule applies to, i.e. in rdf.n3 and rdf.xml, each period (.) replaces a literal character because some SPARQL web clients published before the relevant W3C recommendations produce slightly incorrect "Accept:" strings.)

```
SQL>DB.DBA.URLREWRITE_CREATE_REGEX_RULE (
    'demo_nw_rule2',
    1,
    '(/[^#]*)',
    vector('path'),
    1,
    '/sparql?query=CONSTRUCT+{+%3Chttp%3A//^{URIQADefaultHost}^%U%23this%3E+%3Fp+%3Fo+}+FROM+%3Cht
    vector('path', 'path', '*accept*'),
    null,
    '(text/rdf.n3)|(application/rdf.xml)',
```

```
    0,
    null
    );
```

Note

The request URL for the SPARQL web service looks terrible because it is URL-encoded; the sprintf format string for it is even worse! The easiest way of composing encoded strings of this sort is to use the Conductor UI for configuring the rewrite rules. Alternatively open the SPARQL endpoint page (assuming it supports a UI for entering queries, if no query string is specified), type in the desired CONSTRUCT or DESCRIBE statement into the web form (using some sample URI), execute it, cut the URL of the page with results from the address line of the browser window, paste it into the script and then replace the host name with *^{URIQADefaultHost}^* , every percent with double percent, the parts of the sample IRI to be substituted with *%U* ; finally adjust the vector of replacement parameters so that its length is equal to the number of *%U* or other format specifiers in the template.

The next rule redirects to the RDF browser service to display a description of the subject URI and let the user explore related subjects.

```
SQL>DB.DBA.URLREWRITE_CREATE_REGEX_RULE (
    'demo_nw_rule1',
    1,
    '(/[^#]*)',
    vector('path'),
    1,
    '/rdfbrowser/index.html?uri=http%%3A//^{URIQADefaultHost}^%U%%23this',
    vector('path'),
    null,
    '(text/html)|(\\*/\\*)',
    0,
    303
    );
```

This next rule removes any trailing slash from the input path. Note that *\x24* is the hex character code for the end-of-line pattern *$* . It is written escaped because the dollar sign indicates the beginning of macro in ISQL.

```
SQL>DB.DBA.URLREWRITE_CREATE_REGEX_RULE (
    'demo_nw_rule3',
    1,
    '(/[^#]*)/\x24',
    vector('path'),
    1,
    '%s',
    vector('path'),
    null,
    null,
    0,
    null
    );
```

To configure the server to furnish the ontology underpinning the example Northwind Linked Data View, the procedure LOAD_NW_ONTOLOGY_FROM_DAV, listed below, takes the ontology described in file /DAV/VAD/demo/sql/nw.owl and loads it into graph http://demo.openlinksw.com/schemas/NorthwindOntology/1.0/ in the local quad store. A rewrite rule is then created to query this graph when the input path identifies entities from this ontology.

```
SQL>create procedure DB.DBA.LOAD_NW_ONTOLOGY_FROM_DAV()
{
  declare content1, urihost varchar;
  SELECT cast (RES_CONTENT as varchar) INTO content1 from WS.WS.SYS_DAV_RES WHERE RES_FULL_PATH = '/DAV/V
  DB.DBA.RDF_LOAD_RDFXML (content1, 'http://demo.openlinksw.com/schemas/northwind#', 'http://demo.openlin
  urihost := cfg_item_value(virtuoso_ini_path(), 'URIQA','DefaultHost');
  if (urihost = 'demo.openlinksw.com')
  {
    DB.DBA.VHOST_REMOVE (lpath=>'/schemas/northwind');
    DB.DBA.VHOST_DEFINE (lpath=>'/schemas/northwind', ppath=>'/DAV/VAD/demo/sql/nw.owl', vsp_user=>'dba',
    DB.DBA.VHOST_REMOVE (lpath=>'/schemas/northwind#');
    DB.DBA.VHOST_DEFINE (lpath=>'/schemas/northwind#', ppath=>'/DAV/VAD/demo/sql/nw.owl', vsp_user=>'dba'
  }
};

DB.DBA.LOAD_NW_ONTOLOGY_FROM_DAV();
```

```
drop procedure DB.DBA.LOAD_NW_ONTOLOGY_FROM_DAV;

DB.DBA.URLREWRITE_CREATE_REGEX_RULE (
    'demo_nw_rule4',
    1,
    '/schemas/northwind#(.*)',
    vector('path'),
    1,
    '/sparql?query=DESCRIBE%20%3Chttp%3A//demo.openlinksw.com/schemas/northwind%23%U%3E%20FROM%20%3Chttp%
    vector('path'),
    null,
    '(text/rdf.n3)|(application/rdf.xml)',
    0,
    null
    );
```

Next we define virtual directory */Northwind* and associate with this a rulelist containing the URL rewriting rules defined above. Requests matching the rewriting rules should then be properly redirected to produce the requested data. Attempts to access the virtual directory root will execute the application's default VSP page, namely *sfront.vspx* .

```
SQL>DB.DBA.URLREWRITE_CREATE_RULELIST (
    'demo_nw_rule_list1',
    1,
    vector (
                'demo_nw_rule1',
                'demo_nw_rule2',
                'demo_nw_rule3',
                'demo_nw_rule4'
          ));

VHOST_REMOVE (lpath=>'/Northwind');
DB.DBA.VHOST_DEFINE (lpath=>'/Northwind', ppath=>'/DAV/home/demo/', vsp_user=>'dba', is_dav=>1, def_page=
          is_brws=>0, opts=>vector ('url_rewrite', 'demo_nw_rule_list1'));
```

Finally, to register the namespace prefix *northwind* as persistent we execute:

```
SQL>DB.DBA.XML_SET_NS_DECL ('northwind', 'http://demo.openlinksw.com/schemas/northwind#', 2);
```

Sponger Proxy URI Service

In certain cases, such as Ajax applications, it's prohibited to issue HTTP requests to a server other than the original server. In other cases it is necessary to transform the content of a target to an RDF format. To this end Virtuoso Server provides a Sponger Proxy URI Service. This service takes as an argument a target URL and may return the target's content "as is" or the Sponger may try to transform the content and return an RDF representation of the target. When transforming to RDF, the RDF format (RDF/XML, N3, TURTLE etc) of the output can be forced by a URL parameter or by content negotiation.

When the cartridges_dav.vad package is installed, Virtuoso reserves the path '/about/[id|html|data|rdf]/http/' for the RDF proxy service. In the current implementation, Virtuoso defines virtual directories for HTTP requests that come to the port specified as 'ServerPort' in the '[HTTPServer]' section of Virtuoso configuration file and refer to the above path string. So, if the Virtuoso installation on host example.com listens for HTTP requests on port 8080, client applications should use the 'service endpoint' string equal to 'http://example.com:8080/about/[id|html|data|rdf]/http/'.

If the cartridges_dav.vad VAD package is not installed, then the path '/proxy/rdf/' is used for the Sponger Proxy URI Service.

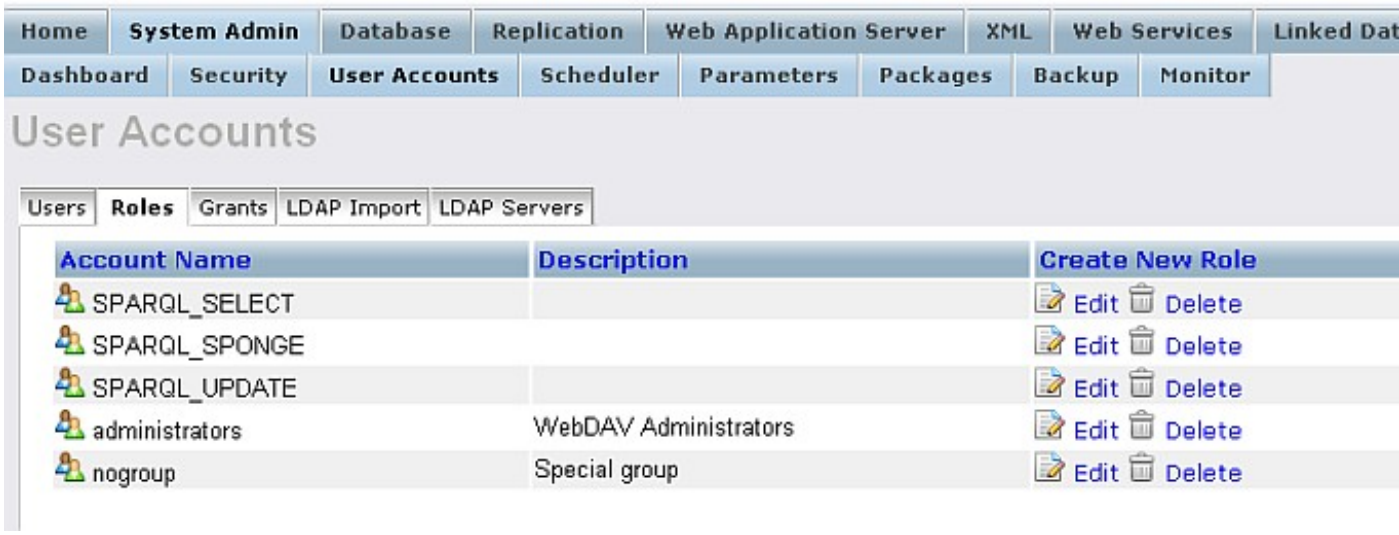
The old pattern for the Sponger Proxy URI Service, '/proxy/', is now deprecated.

Note: If you do not have the cartridges package installed, in order for the Sponger Proxy URI Service to work correctly, you must grant the SPARQL_UPDATE role to user SPARQL and grant execute permission on procedure RDF_SPONGE_UP.

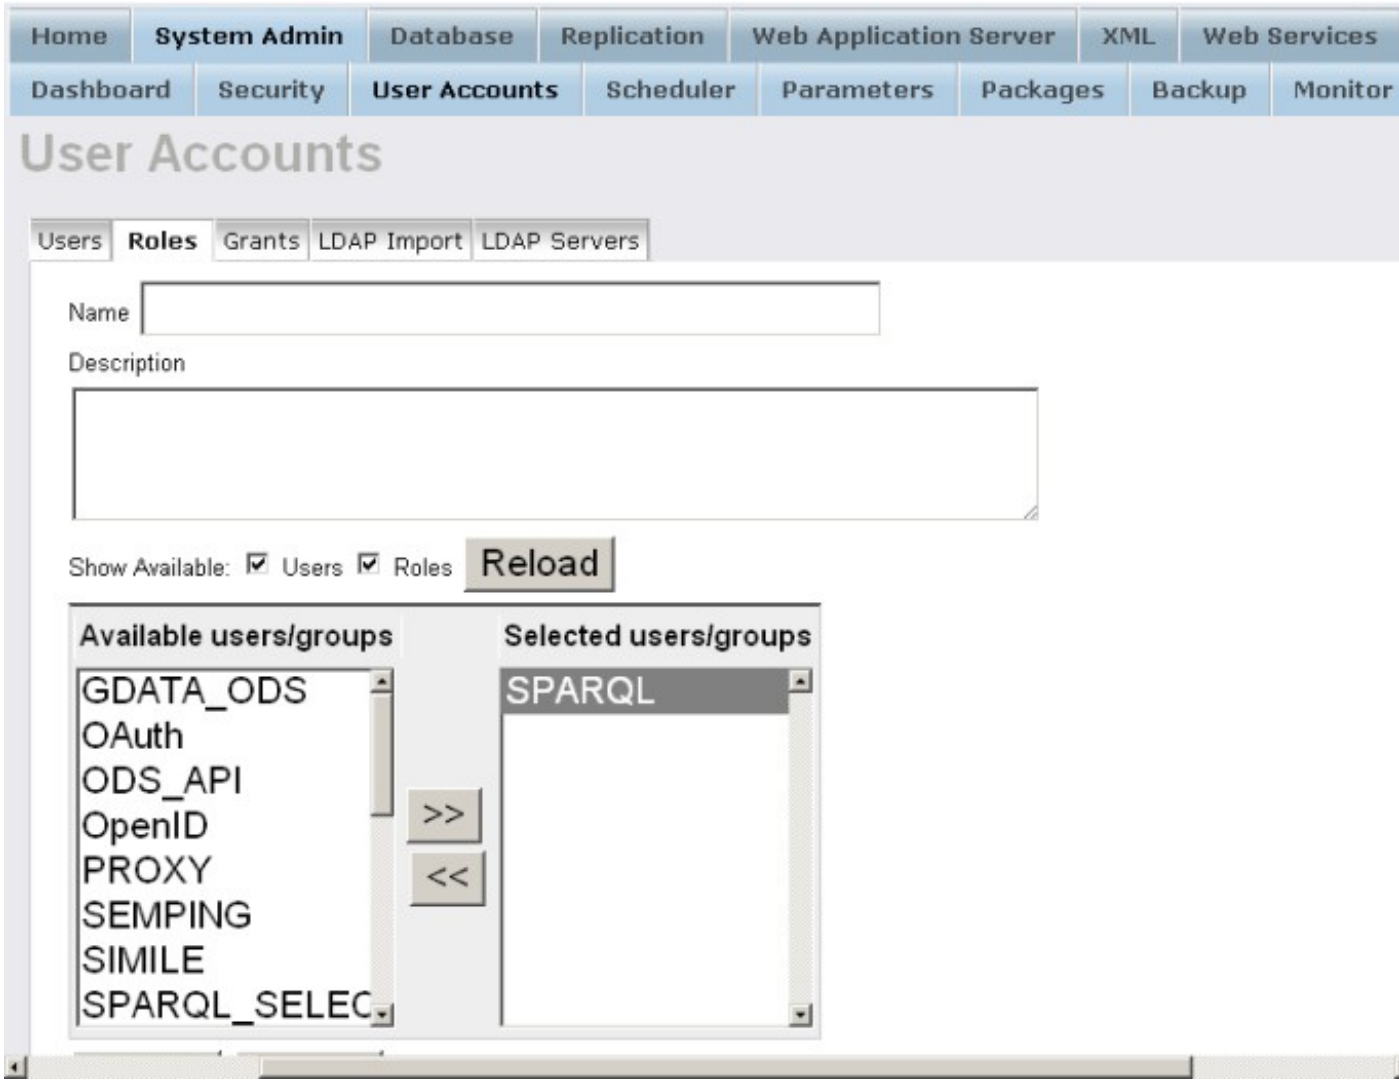
To enable SPARQL_UPDATE using the Conductor UI:

1. Go to the Virtuoso Administration Conductor i.e. http://host:port/conductor
2. Login as dba user
3. Go to System Admin->User Accounts->Roles

4. **Figure 16.36. Conductor UI**



5. Click the link "Edit" for "SPARQL_UPDATE
6. Select from the list of available user/groups "SPARQL" and click the ">>" button so to add it to the right-positioned list.
7. **Figure 16.37. Conductor UI**



8. Click the button "Update".

To grant execute permission on RDF_SPONGE_UP:

```
grant execute on DB.DBA.RDF_SPONGE_UP to "SPARQL";
```

When invoked with a URL of the form http://host:port/proxy?..., the Sponger Proxy URI Service accepts the following query string parameters:

- *force*

  - if 'rdf' is specified, the Sponger will try to extract RDF data from the target and return it
- *header*

  - HTTP headers to be sent to the target
- *output-format*

  - if 'force=rdf' is given, designates the desired output MIME type of the RDF data. The default is 'rdf+xml'. Other supported MIME types are 'n3', 'turtle' or 'ttl'.

When RDF data is requested and 'output-format' is not specified, the result will be serialized with a MIME type determined by the request 'Accept' headers i.e. the proxy service will do content negotiation.

Example: RDF file with URL: http://www.w3.org/People/Berners-Lee/card

```
-- Access the url in order to view the result in HTML format:
http://host:port/about/html/http/www.w3.org/People/Berners-Lee/card
-- Access the url in order to view the result in RDF:
http://host:port/about/rdf/http://www.w3.org/People/Berners-Lee/card
-- or use the following proxy invocation style:
http://host:port/proxy/rdf/http://www.w3.org/People/Berners-Lee/card
-- or this one:
http://host:port/proxy?url=http://www.w3.org/People/Berners-Lee/card&force=rdf
```

Note: It is not permitted, when using the style http://host:port/proxy/rdf, to pass URL query string parameters to the proxy.

Now go to the SPARQL endpoint, i.e. http://host:port/sparql

For the 'Default Graph URI' enter the URL of the RDF file: http://www.w3.org/People/Berners-Lee/card

For 'Query' enter:

```
SELECT *
WHERE
  {
    ?s ?p ?o
  }
```

Query result:

```
s                                                p                                                o
http://www.w3.org/People/Berners-Lee/card        http://www.w3.org/1999/02/22-rdf-syntax-ns#type  http:/
http://www.w3.org/People/Berners-Lee/card        http://purl.org/dc/elements/1.1/title            Tim Be
http://www.w3.org/People/Berners-Lee/card        http://creativecommons.org/ns#license            http:/
http://www.w3.org/People/Berners-Lee/card        http://xmlns.com/foaf/0.1/maker                  http:/
etc ...
```

SPARQL INI service

The [SPARQL] section of the virtuoso.ini configuration file sets parameters and limits for the SPARQL query web service. The values contained in the [SPARQL] section can be exposed in RDF form via the URL pattern http://cname/sparql?ini

Example: http://demo.openlinksw.com/sparql?ini

```
<?xml version="1.0" encoding="utf-8" ?>
<rdf:RDF xmlns:rdf="http://www.w3.org/1999/02/22-rdf-syntax-ns#" xmlns:rdfs="http://www.w3.org/2000/01/rd
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:MaxQueryCostEstima
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:ExternalXsltSource
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:DefaultQuery xmlns
```

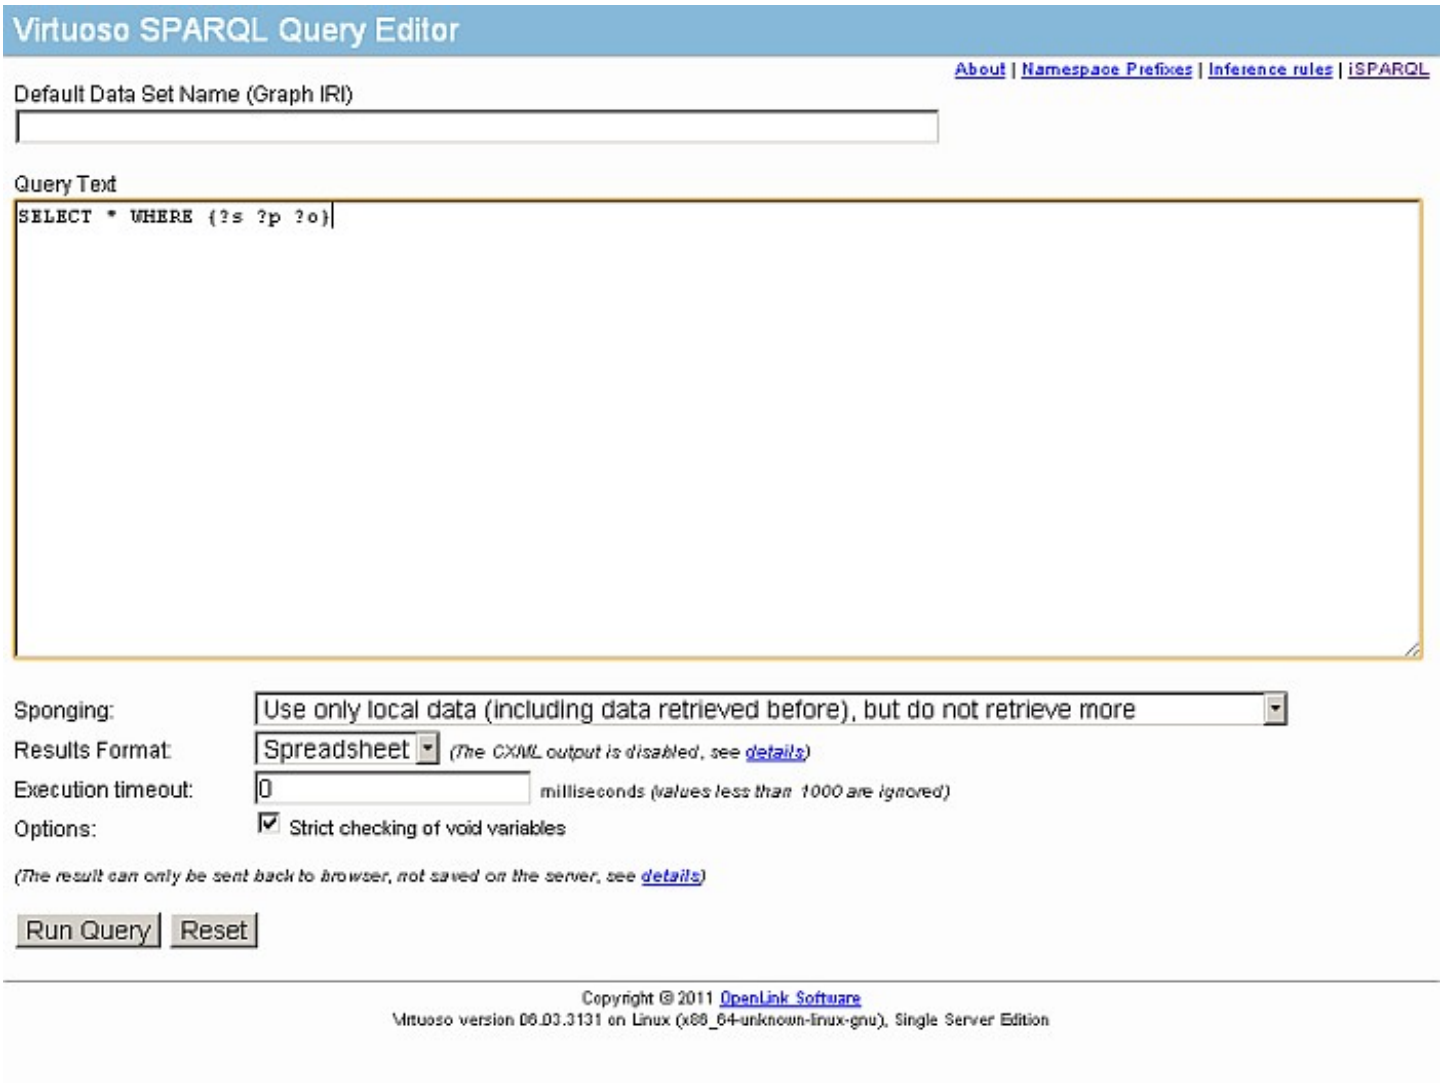
```
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:ResultSetMaxRows x
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:MaxQueryExecutionT
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:ExternalQuerySourc
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:DefaultGraph xmlns
<rdf:Description rdf:about="http://www.openlinksw.com/schemas/virtini#SPARQL"><ns0pred:PingService xmlns:
</rdf:RDF>
```

SPARQL Endpoint with Excel MIME Type Output Option

The SPARQL endpoint offers an Excel MIME type output option.

From http://cname:host/sparql, select "Spreadsheet" for the "Display Results As:" option and click the "Run Query" button.

Figure 16.38. SPARQL Endpoint with Excel MIME type output



The resulting query string contains a format parameter value of *"application/vnd.ms-excel"* . For example, A URL such as this one will be generated, and can be opened directly with Excel.

Figure 16.39. SPARQL Endpoint with Excel MIME type output

	A	B
1	URI	ObjectType
2	http://demo.openlinksw.com/dataspace/person/demo	http://xmlns.com/foaf/0.1/PersonalProfileDocument

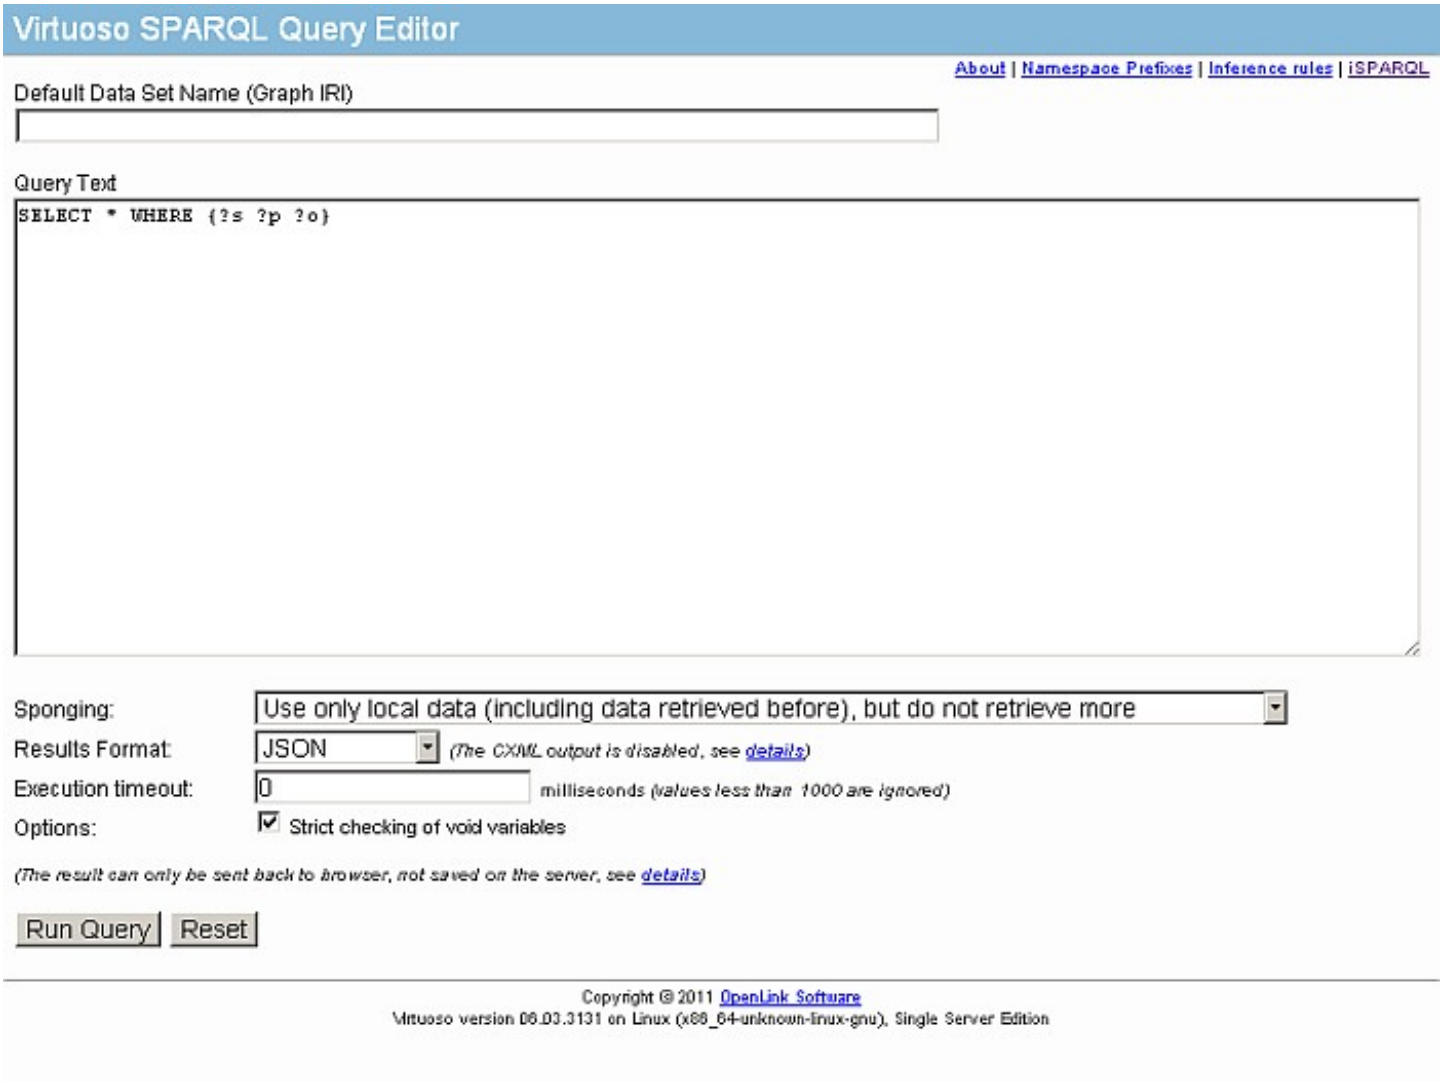
SPARQL Endpoint with RDF+JSON Output: SPARQL UI Example

The SPARQL endpoint also offers a RDF+JSON output option.

From http://cname:host/sparql select "JSON" for "Display Results As:" and click the "Run Query" button.

Figure 16.40. SPARQL Endpoint with RDF+JSON output



As result URL containing as parameter the format *application/sparql-results+json* will be generated and the content should look like:

Figure 16.41. SPARQL Endpoint with JSON+RDF

```
{ "head": { "link": [], "vars": ["s", "p", "o"] },
  "results": { "distinct": false, "ordered": true, "bindings": [
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo" }       , "p": { "type'
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo" }       , "p": { "type'
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo" }       , "p": { "type'
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo" }       , "p": { "type'
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo#event" } , "p": { "type'
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo#event" } , "p": { "type'
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo#based_near" }    , "p":
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo#based_near" }    , "p":
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo#based_near" }    , "p":
    { "s": { "type": "uri", "value": "http://demo.openlinksw.com/dataspace/person/demo#org" }   , "p": { "type'
```

SPARQL Endpoint with JSON/P Output Option: Curl Example

The SPARQL endpoint also offers a JSON/P output option.

The SPARQL endpoint accepts a 'callback' URL parameter and in this case when parameter 'format' is 'json', then it will produce JSON/P output.

```
$ curl "http://lod.openlinksw.com/sparql?query=select+*+where+\{+%3Fx+a+%3Fz+.+\}+limit+10&format=json&de
func(

{ "head": { "link": [], "vars": ["x", "z"] },
  "results": { "distinct": false, "ordered": true, "bindings": [
```

```
    { "x": { "type": "bnode", "value": "nodeID://b196899188" }  , "z": { "type": "uri", "value": "http://

    { "x": { "type": "uri", "value": "http://www.wasab.dk/morten/2005/04/sparqlette/#profile" } , "z": {
services/owl-s/1.1/Service.owl#ServiceProfile" }},
    { "x": { "type": "uri", "value": "http://www.wasab.dk/morten/2003/12/nearestAirport/#b-profile" }   ,

```

16.2.4. Troubleshooting SPARQL Queries

A short SPARQL query can be compiled into a long SQL statement, especially if data comes from many quad map patterns. A moderately sized application with 50 tables and 10 columns per table may create thousands of quad map patterns for subjects spanning hundreds of different types. An attempt to "select everything" from Linked Data View of that complexity may easily create 5000 lines of SQL code. Thus it is to be expected that some queries will be rejected even if the same queries would work fine if the RDF data were held as physical quads in default storage, rather than synthesized through an Linked Data View.

In addition, the SQL compiler catches typos efficiently, signalling an error if a table or column name is unknown, efficiently catching typos. SPARQL uses IRIs that are long and sometimes unreadable, but there is no "closed world" schema of the data so a typo in an IRI is not an error; it is simply some other IRI. So a typo in an IRI or in a namespace prefix causes missing bindings of some triple patterns of the query and an incomplete result, but usually no errors are reported. A typo in graph or predicate IRI may cause the SPARQL compiler to generate code that accesses default (quad) storage instead of a relational source or generate empty code that accesses nothing.

The SQL compiler does not signal casting errors when it runs the statement generated from SPARQL, because the generated SQL code contains *option (QUIETCAST)* . This means that mismatches between expected and actual datatypes of values stay invisible and may cause rounding errors (e.g. integer division instead of floating-point) and even empty joins (due to join conditions that silently return NULL instead of returning a comparison error).

In other words, SPARQL queries are so laconic that there is no room for details that let the compiler distinguish between intent and a bug. This masks query complexity, misuse of names and type mismatches. One may make debugging easier by making queries longer.

Two very helpful debugging tools are automatic void variable recognition and plain old code inspection. "Automatic" means "cheap" so the very first step of debugging is to ensure that every triple pattern of the query may in principle return something. This helps in finding typos when the query gets data from Linked Data Views. It also helps when a query tries to join two disjoint sorts of subjects. If the *define sql:signal-void-variables 1* directive is placed in the preamble of the SPARQL query, the compiler will signal an error if it finds any triple pattern that cannot bind variables or any variable that is proved to be always unbound. This is especially useful when data are supposed to come from an *option (exclusive)* or *option (soft exclusive)* quad map. Without one of these options, the SPARQL compiler will usually bind variables using "physical quads"; the table of physical quads may contain any rows that match any given triple pattern; thus many errors will remain undiscovered. If the name of a quad map pattern is known then it is possible to force the SPARQL compiler to use only that quad map for the whole query or a part of the query. This is possible by using the following syntax:

```
QUAD MAP quad-map-name { group-pattern }
```

If some triple pattern inside *group-pattern* cannot be bound using *quad-map-name* or one of its descendants then *define sql:signal-void-variables 1* will force the compiler to signal the error.

Note

Although it is technically possible to use *QUAD MAP* to improve the performance of a query that tries to access redundant Linked Data Views, it is much better to achieve the same effect by providing a more restrictive query or by

Note

changing/extending the Linked Data View. If an application relies on this trick then interoperable third-party SPARQL clients may experience problems because they cannot use Virtuoso-specific extensions.

If the automated query checking gives nothing, function `sparql_to_sql_text` can be used in order to get the SQL text generated from the given query. Its only argument is the text of the SPARQL query to compile (without any leading SPARQL keyword or semicolon at the end). The returned value is the SQL text. The output may be long but it is the most authoritative source of diagnostic data.

When called from ISQL or an ODBC client, the return value of `sparql_to_sql_text` may be transferred as a BLOB so ISQL requires the "set blobs on" instruction to avoid data truncation. Even better, the SQL text can be saved to a file:

```
string_to_file ('debug.sql', sparql_to_sql_text ('SELECT * WHERE { graph ?g { ?s a ?type }}'), -2);
```

(The -2 is to overwrite the previous version of the file, as this function may be called many times).

Note

When passing the query text to sparql_to_sql_text, if the query contains single quotes, each embedded single quote must be doubled up. Use double quotes in SPARQL queries to avoid this inconvenience.

As an example, let's find out why the query

```
SQL>SPARQL
PREFIX northwind: <http://demo.openlinksw.com/schemas/northwind#>
SELECT DISTINCT ?emp
FROM <http://myhost.example.com/Northwind>
WHERE {
    ?order1 northwind:has_salesrep ?emp ; northwind:shipCountry ?country1 .
    ?order2 northwind:has_salesrep ?emp ; northwind:shipCountry ?country2 .
    filter (?country1 != ?country2) }
```

is much slower than a similar SQL statement. The call of `sparql_to_sql_text` returns the equivalent SQL statement:

```
SELECT DISTINCT sprintf_iri ( 'http://myhost.example.com/Northwind/Employee/%U%U%d#this' ,
    /*retval[*/ "s-6-1-t0"."b067b7d~FirstName~0" /* emp */ /*]retval*/ ,
    /*retval[*/  "s-6-1-t0"."b067b7d~FirstName~1" /*]retval*/ ,
    /*retval[*/  "s-6-1-t0"."b067b7d~FirstName~2" /*]retval*/ ) AS /*tmpl*/ "emp"
FROM (SELECT "s-6-1-t0-int~orders"."OrderID" AS /*tmpl*/ "20ffecc~OrderID",
         "s-6-1-t0-int~employees"."FirstName" AS /*as-name-N*/ "b067b7d~FirstName~0",
         "s-6-1-t0-int~employees"."LastName" AS /*as-name-N*/ "b067b7d~FirstName~1",
         "s-6-1-t0-int~employees"."EmployeeID" AS /*as-name-N*/ "b067b7d~FirstName~2"
         FROM Demo.demo.Employees AS "s-6-1-t0-int~employees", Demo.demo.Orders AS "s-6-1-t0-int~orders"
         WHERE /* inter-alias join cond */
       "s-6-1-t0-int~orders".EmployeeID = "s-6-1-t0-int~employees".EmployeeID) AS "s-6-1-t0",
    (SELECT "s-6-1-t1-int~orders"."OrderID" AS /*tmpl*/ "20ffecc~OrderID",
        "s-6-1-t1-int~orders"."ShipCountry" AS /*tmpl*/ "e45a7f~ShipCountry"
        FROM Demo.demo.Orders AS "s-6-1-t1-int~orders") AS "s-6-1-t1",
    (SELECT "s-6-1-t2-int~orders"."OrderID" AS /*tmpl*/ "20ffecc~OrderID",
        "s-6-1-t2-int~employees"."FirstName" AS /*as-name-N*/ "b067b7d~FirstName~0",
        "s-6-1-t2-int~employees"."LastName" AS /*as-name-N*/ "b067b7d~FirstName~1",
        "s-6-1-t2-int~employees"."EmployeeID" AS /*as-name-N*/ "b067b7d~FirstName~2"
        FROM Demo.demo.Employees AS "s-6-1-t2-int~employees", Demo.demo.Orders AS "s-6-1-t2-int~orders"
    WHERE /* inter-alias join cond */
       "s-6-1-t2-int~orders".EmployeeID = "s-6-1-t2-int~employees".EmployeeID) AS "s-6-1-t2",
    (SELECT "s-6-1-t3-int~orders"."OrderID" AS /*tmpl*/ "20ffecc~OrderID",
        "s-6-1-t3-int~orders"."ShipCountry" AS /*tmpl*/ "e45a7f~ShipCountry"
    FROM Demo.demo.Orders AS "s-6-1-t3-int~orders") AS "s-6-1-t3"
WHERE /* two fields belong to same equiv */
    /*retval[*/  "s-6-1-t0"."20ffecc~OrderID" /* order1 */ /*]retval*/  =
    /*retval[*/  "s-6-1-t1"."20ffecc~OrderID" /* order1 */ /*]retval*/
    AND /* two fields belong to same equiv */
    sprintf_iri ( 'http://myhost.example.com/Northwind/Employee/%U%U%d#this' ,
        /*retval[*/  "s-6-1-t0"."b067b7d~FirstName~0" /* emp */ /*]retval*/ ,
        /*retval[*/  "s-6-1-t0"."b067b7d~FirstName~1" /*]retval*/ ,
        /*retval[*/  "s-6-1-t0"."b067b7d~FirstName~2" /*]retval*/ ) =
    sprintf_iri ( 'http://myhost.example.com/Northwind/Employee/%U%U%d#this' ,
        /*retval[*/  "s-6-1-t2"."b067b7d~FirstName~0" /* emp */ /*]retval*/ ,
        /*retval[*/  "s-6-1-t2"."b067b7d~FirstName~1" /*]retval*/ ,
        /*retval[*/  "s-6-1-t2"."b067b7d~FirstName~2" /*]retval*/ )
    AND /* two fields belong to same equiv */
```

```
    /*retval[*/  "s-6-1-t2"."20ffecc~OrderID" /* order2 */ /*]retval*/  =
    /*retval[*/  "s-6-1-t3"."20ffecc~OrderID" /* order2 */ /*]retval*/
    AND /* filter */
   ( /*retval[*/  "s-6-1-t1"."e45a7f~ShipCountry" /* country1 */ /*]retval*/  <>
       /*retval[*/  "s-6-1-t3"."e45a7f~ShipCountry" /* country2 */ /*]retval*/ )
OPTION (QUIETCAST)
```

The query is next to unreadable but some comments split it into meaningful expressions. Every triple (or list of similar triples) becomes a subquery that returns fields needed to build the values of bound variables. The fields are printed wrapped by comments like */*retval[*/ expression /* original variable name */ /*]retval*/* . Names like*"s-6-1-t0"* contain the source line number where a group pattern begins (6) and the serial number of the triple (0). Comment */* inter-alias join cond */* means that the expression which follows is the condition as written in the declaration of the quad map pattern. Comment */* filter */* precedes expressions for FILTER expressions in the source SPARQL. The word "equiv" means "equivalence class", i.e. a group of occurrences of variables in the source query such that all occurrences are bound to the same value. E.g. when a name repeats in many triples of a group, all its occurrences form an equivalence class. In some cases the compiler can prove that two variables are always equal even if the names differ - these variables are also placed into an "equiv".

Looking at this query, you may notice equalities like *sprintf_iri (...) = sprintf_iri (...)* . That is sub-optimal because it indicates that no index will be used to optimize the join and that there will be one function call per row. When the variable *?emp* appears in two different triples, it means that the value of the variable is the same in both triples. The query compares IRIs instead of comparing the arguments of `sprintf_iri` because the format string is not proven to be a bijection. Indeed it cannot be a bijection for *arbitrary* strings, but the database must reflect the real world. If it is assumed that the real names of persons never start with a digit, within the *%d%U* format fragment, the digits will always be distinguishable from the name; so the IRI class can be declared as a bijection even if it is not true for arbitrary strings. The script can then include "suspicious" *option (bijection)* as follows:

```
create iri class sample:Employee "http://example.com/Employee/%d%U#this"
  (in employee_id integer not null, in employee_lastname varchar not null)
  option (bijection) .
```

Unfortunately, attempts to use the same trick with the declaration from the Northwind example will fail:

```
create iri class northwind:Employee "http://^{URIQADefaultHost}^/Northwind/Employee/%U%U%d#this"
  (in employee_firstname varchar not null, in employee_lastname varchar not null, in employee_id integer
  option (bijection) .
```

Bijection will allow the parsing, but it will never give the proper result, because the first *%U* will read the whole concatenation of *%U%U%d* , leaving nothing before the*#this* for the second *%U* (this is an error) and leaving nothing for the *%d* (that is an explicit parse error, becauses the integer field cannot be empty).

The string parser will process the string from left to right so it will be unable to parse the string. The compiler might sometimes report an error if it can prove that the format string is not appropriate for bijection.

The correct way of improving the Northwind example is to enable reliable bijection by adding strong delimiters:

```
create iri class northwind:Employee "http://^{URIQADefaultHost}^/Northwind/Employee/%U/%U/%d#this"
  (in employee_firstname varchar not null, in employee_lastname varchar not null, in employee_id integer
  option (bijection) .
```

After running the updated script, the query contains three comparisons of fields that were arguments of `sprintf_iri` in the previous version.

Example for casting string as IRI type

```
create function DB.DBA.RDF_DF_GRANTEE_ID_URI (in id integer)
{
  declare isrole integer;
  isrole := coalesce ((SELECT top 1 U_IS_ROLE FROM DB.DBA.SYS_USERS WHERE U_ID = id));
  if (isrole is null)
    return NULL;
  else if (isrole)
    return sprintf ('http://%s/sys/group?id=%d', registry_get ('URIQADefaultHost'), id);
  else
    return sprintf ('http://%s/sys/user?id=%d', registry_get ('URIQADefaultHost'), id);
}
;
```

```
grant execute on DB.DBA.RDF_DF_GRANTEE_ID_URI to SPARQL_SELECT
;

create function DB.DBA.RDF_DF_GRANTEE_ID_URI_INVERSE (in id_iri varchar)
{
  declare parts any;
  parts := sprintf_inverse (id_iri, sprintf ('http://%s/sys/user?id=%%d', registry_get ('URIQADefaultHost
  if (parts is not null)
    {
      if (exists (SELECT TOP 1 1 FROM DB.DBA.SYS_USERS WHERE U_ID = parts[0] and not U_IS_ROLE))
        return parts[0];
    }
  parts := sprintf_inverse (id_iri, sprintf ('http://%s/sys/group?id=%%d', registry_get ('URIQADefaultHos
  if (parts is not null)
    {
      if (exists (SELECT TOP 1 1 FROM DB.DBA.SYS_USERS WHERE U_ID = parts[0] and U_IS_ROLE))
        return parts[0];
    }
  return NULL;
}
;

grant execute on DB.DBA.RDF_DF_GRANTEE_ID_URI_INVERSE to SPARQL_SELECT
;

create iri class oplsioc:grantee_iri using
  function DB.DBA.RDF_DF_GRANTEE_ID_URI (in id integer) returns varchar ,
  function DB.DBA.RDF_DF_GRANTEE_ID_URI_INVERSE (in id_iri varchar) returns integer
  option ( bijection ,
    returns     "http://^{URIQADefaultHost}^/sys/group?id=%d"
    union       "http://^{URIQADefaultHost}^/sys/user?id=%d" ) .
```

16.2.5. SPARQL Inline in SQL

Virtuoso extends the SQL 92 syntax with SPARQL queries and subqueries. Instead of writing a SQL SELECT query or subquery, one can write the SPARQL keyword and a SPARQL query after the keyword.

```
SQL>SPARQL SELECT DISTINCT ?p WHERE { graph ?g { ?s ?p ?o } };
p
varchar
----------
http://example.org/ns#b
http://example.org/ns#d
http://xmlns.com/foaf/0.1/name
http://xmlns.com/foaf/0.1/mbox
...

SQL>SELECT distinct subseq ("p", strchr ("p", '#')) as fragment
  FROM (SPARQL SELECT DISTINCT ?p WHERE { graph ?g { ?s ?p ?o } } ) as all_predicates
  WHERE "p" like '%#%';
fragment
varchar
----------
#query
#data
#name
#comment
...
```

Note that names of variables returned from SPARQL are always case-sensitive and no case mode rules apply to them. Depending on the CaseMode parameter in the Virtuoso configuration file, double quotes should be used if necessary to refer to them in surrounding SQL code.

It is possible to pass parameters to a SPARQL query via a Virtuoso-specific syntax extension. *??* or *$?* indicates a positional parameter similar to *?* in plain SQL. *??* can be used in graph patterns or anywhere in place of a SPARQL variable. The value of a parameter should be passed in SQL form, i.e. this should be a number or a untyped string. An IRI ID can be passed in all cases where an absolute IRI can, except the obvious case of when the variable is an argument of a function that requires string. If the parameter is used in the 'graph', 'subject' or 'object' position of the SPARQL pattern, the string parameter is converted into an IRI automatically. In other cases an IRI string is indistinguishable from a string literal, so it is necessary to call the built-in SPARQL

function *iri()* , e.g. *iri (??)* . Using this notation, any dynamic SQL client (whether ODBC, JDBC or some other) can execute parameterized SPARQL queries, binding parameters just as with dynamic SQL.

```
SQL> create function param_passing_demo ()
{
  declare stat, msg varchar;
  declare mdata, rset any;
  exec ('SPARQL SELECT ?s WHERE { graph ?g { ?s ?? ?? }}',
    stat, msg,
    vector ( /* Vector of two parameters */
      'http://www.w3.org/2001/sw/DataAccess/tests/data/Sorting/sort-0#int1',
      4 ),
    10, /* Max no of rows */
    mdata, /* Variable to get metadata */
    rset ); /* Variable to get result-set */
  if (length (rset) = 0)
    signal ('23000',
      'No data found, try demo database with installed Virtuoso tutorials');
  return rset[0][0];
}

SQL> SELECT param_passing_demo ();
callret
VARCHAR
_______________________________________________________________________________

http://www.w3.org/2001/sw/DataAccess/tests/data/Sorting/sort-0#four

1 Rows. -- 00000 msec.
```

Another example:

```
INSERT INTO GRAPH <http://example.com/Northwind>
{ `iri($?)` <http://example.com/schemas/northwind#has_province> "Valencia" };
```

An inline SPARQL query can refer to SQL variables that are in scope in the SQL query or stored procedure containing it. Virtuoso extends the SPARQL syntax with a special notation to this effect. A reference to SQL variable X can be written as *?:X* or *$:X* . A reference to column *C* of a table or a sub-select with alias *T* can be written as *?:T.C* or *$:T.C* . Both notations can be used in any place where a variable name is allowed, except the 'AS' clause described below.

A column of a result set of a SPARQL SELECT can be used in SQL code inside a for statement just like any column from a SQL select.

SQL rules about double-quoted names are applicable to variables that are passed to a SPARQL query or selected from one. If a variable name contains unusual characters or should not be normalized according to SQL conventions then the name should use double quotes for escaping. e.g., the notation *?:"OrderLine"* will always refer to variable or column titled *OrderLine* whereas *?:OrderLine* can be converted to *ORDERLINE* or *orderline* .

It is safer to avoid using variable names that conflict with column names of RDF system tables, esp. *G* , *S* , *P* and *O* . These names are not reserved now but they may cause subtle bugs when an incorrect SPARQL subquery is compiled into SQL code that refers to identically named table columns. Some of these names may be rejected as syntax errors by future Virtuoso versions.

```
SQL> create procedure sql_vars_demo ()
{
#pragma prefix sort0: <http://www.w3.org/2001/sw/DataAccess/tests/data/Sorting/sort-0#>
  declare RES varchar;
  declare obj integer;
  result_names (RES);
  obj := 4;
  for (SPARQL SELECT ?subj WHERE { graph ?g { ?subj sort0:int1 ?:obj } } ) do
    result ("subj");
}

SQL> sql_vars_demo ();
RES
VARCHAR
_______________________________________________________________________________

http://www.w3.org/2001/sw/DataAccess/tests/data/Sorting/sort-0#four
```

```
1 Rows. -- 00000 msec.
```

The example also demonstrates the Virtuoso/PL pragma line for procedure-wide declarations of namespace prefixes. This makes the code more readable and eliminates duplicate declarations of namespace prefixes when the procedure contains many SPARQL fragments that refer to a common set of namespaces.

A SPARQL ASK query can be used as an argument of the SQL EXISTS predicate.

```
create function sparql_ask_demo () returns varchar
{
  if (exists (sparql ask where { graph ?g { ?s ?p 4}}))
    return 'YES';
  else
    return 'NO';
}

SQL> SELECT sparql_ask_demo ();
_____________________________________________________________________________

YES
```

Controlling SPARQL Output Data Types

The compilation of a SPARQL query may depend on an environment that is usually provided by the SPARQL protocol and which includes the default graph URI. Environment settings that come from the SPARQL protocol may override settings in the text of a SPARQL query. To let an application configure the environment for a query, SPARQL's syntax has been extended with the 'define' clause:

```
define parameter-qname parameter-value
```

Examples of supported parameters are *output:valmode* and *output:format*

output:valmode specifies which data types (i.e. representation) should be used for values in the result set. The default is "SQLVAL", meaning that a query returns result set values in SQL format and behaves as a typical SQL select - IRIs and string literals are returned as strings, making the output compatible with ODBC and the standard SQL routines. To compose triple vectors in Virtuoso PL code, an application may need data in long format. A valmode of "LONG" means that IRIs are returned as IRI_IDs and string literals may be returned as special "RDF boxes" even if they are actually plain strings. This may cause problems if these new datatypes are not known to the data recipient or if IRIs come from RDF Views (in which case IRI_IDs are created on the fly and 'pollute' the database), but it can result in fewer data conversions and thus better speed if used properly. "AUTO" disables all types of conversion for the result set, so the latter can comprise a mix of values across "SQLVAL" and "LONG" value modes, as well as some internal representations. It is better to avoid using this mode in user applications because the output may change from version to version.

If the query contains a

```
define output:valmode 'LONG'
```

clause then all returned values are in long format. e.g., the following query returns IRI_ID's instead of IRI strings.

```
SQL>SPARQL define output:valmode 'LONG' SELECT distinct ?p WHERE { graph ?g { ?s ?p ?o } };
p
----------
#i1000001
#i1000003
#i1000005
#i1000006
...
```

output:format instructs the SPARQL compiler that the result of the query should be serialized into an RDF document - that document will be returned as a single column of a single row result set. *output:format* is especially useful if a SPARQL CONSTRUCT or SPARQL DESCRIBE query is executed directly via an ODBC or JDBC database connection and the client cannot receive the resulting dictionary of triples (there's no way to transfer such an object via ODBC). Using this option, the client can receive the document that contains the whole result set of a SELECT or the dictionary of triples of a CONSTRUCT/DESCRIBE, and parse it locally.

Supported values for *output:format* are *RDF/XML* and *TURTLE* (or *TTL*). If both *output:valmode* and *output:format* are specified, *output:format* has higher priority, raising an error if *output:valmode* is set to a value other than *LONG* .

When a SPARQL query is compiled, the compiler checks whether the result set is to be sent to a remote ODBC/JDBC client or used in some other way. The compiler will automatically set *output:format* to *TURTLE* if compiling for execution by an SQL client.

The example below demonstrates how different values of *output:format* affect the result of SPARQL SELECT. Note 10 rows and 4 columns in the first result, and single LONG VARCHAR in the others. When using the ISQL client, use the 'set blobs on;' directive if fetching long texts to avoid receiving a 'data truncated' warning.

```
SQL> SPARQL SELECT * WHERE {graph ?g { ?s ?p ?o }} limit 10;
g                                             s                    p                              o
VARCHAR                                       VARCHAR              VARCHAR                        VARCHAR

16.2.6. API Functions

SPARQL can be used inline wherever SQL can be used. The only API functions that one needs to know are the ones for loading RDF data into the store. Dynamic SQL client applications can issue SPARQL queries against Virtuoso through the regular SQL client API, ODBC, JDBC or any other supported API, simply by prefixing the SPARQL query with the SPARQL keyword. Parameters work just as with dynamic SQL. Stored procedures can have SPARQL expressions inline and can declare cursors over SPARQL result sets.

Value conversions between SQL and SPARQL are most often automatic and invisible. In some cases one needs to be aware of the different SPARQL value representations (valmodes). SPARQL offers declarations for specifying whether returned graphs are to be serialized as XML or Turtle, or whether these will be hash tables of triples. See `dict_new()` and related functions for a description of the hash table SQL data type. The use of dict's is convenient for further programmatic processing of graphs.

RDF-related procedures use Virtuoso/PL vectors and dictionaries to represent RDF triples and sets of triples.

Valmode means the "format of values returned by an expression", i.e. 'short', 'long' or 'SQL value'.

Triple vector is a vector (array) of S, P and O, where all values are in 'long' formats, i.e. IRI_ID's for IRI values, numbers or datetimes for corresponding XMLSchema types, special "RDF box" objects if O is neither string nor IRI.

Dictionary of triples or *Hash table of triples* is an dictionary object made by the SQL function *dict_new ()* whose keys are triple vectors and values are not specified; this is a good storage format for an unordered set of distinct triples.

Dictionary of blank node names is a dictionary used for tricky processing of a number of TURTLE or RDF /XML descriptions of subgraphs that come from a common graph. Imagine a situation where different descriptions actually refer to the same blank nodes of the original graph and, moreover, the application that generates these descriptions always generates the same blank node id string for the same node. A reader of descriptions can correctly join described subgraphs into one big subgraph by filling in a dictionary that contains blank node id strings as keys and IRI_ID's assigned to those strings as dependent data. The sharing of the same node dictionary by all readers of an application will ensure that no blank node is duplicated.

Data Import

Using TTLP

DB.DBA.TTLP() parses TTL (TURTLE or N3 resource) and places its triples into DB.DBA.RDF_QUAD.

```
create procedure DB.DBA.TTLP (
    in strg any,       -- text of the resource
    in base varchar,   -- base IRI to resolve relative IRIs to absolute
    in graph varchar, -- target graph IRI, parsed triples will appear in that graph.
    in flags int)   -- bitmask of flags that permit some sorts of syntax errors in resource, use 0.
```

For loading a file of any great length, it is more practical to use the file_to_string_output function.

It is important the file be accessible to the Virtuoso server. You need to have set properly set the *DirsAllowed* parameter value in the section [Parameters] of the Virtuoso database INI file. For example on Windows it could be:

```
virtuoso.ini file:
```

```
[Parameters]
...
DirsAllowed =  .\tmp
...
```

So, in the example, the file you want to import from, should be in the tmp folder or in a subfolder. Note that this example folder is a subfolder of the Virtuoso Server working directory.

```
SQL> DB.DBA.TTLP (file_to_string_output ('.\tmp\data.ttl'), '', 'http://my_graph', 0);
```

Using TTLP_MT

The DB.DBA.TTLP_MT() procedure is like DB.DBA.TTLP() but loads the file on multiple threads, using parallel I/O and multiprocessing if available. The function does not leave a transaction log. Hence, after a successful load, one should execute the checkpoint statement to make sure that a server restart does not wipe out the results.

```
create procedure DB.DBA.TTLP_MT (
    in strg any,       -- text of the resource
    in base varchar,   -- base IRI to resolve relative IRIs to absolute
    in graph varchar,  -- target graph IRI, parsed triples will appear in that graph.
    in flags int) -- flags, use 0
```

Using RDF_LOAD_RDFXML_MT

For loading large resources when transactional integrity is not important (loading of a single resource may take more than one transaction) you can use also the *DB.DBA.RDF_LOAD_RDFXML_MT()* procedure:

```
create procedure DB.DBA.RDF_LOAD_RDFXML_MT (
    in strg varchar,  -- text of the resource
    in base varchar,  -- base IRI to resolve relative IRIs to absolute
    in graph varchar) -- target graph IRI, parsed triples will appear in that graph.
```

The following example demonstrates importing data from the RDF resource with URI: http://www.w3.org/People/Berners-Lee/card

```
SQL>create procedure MY_LOAD_FILE (in full_uri varchar, in in_resultset integer := 0)
{
  declare REPORT varchar;
  declare graph_uri, dattext varchar;
  declare app_env any;
  app_env := null;
  whenever sqlstate '*' goto err_rep;
  if (not in_resultset)
    result_names (REPORT);
  dattext := cast (XML_URI_GET_AND_CACHE (full_uri) as varchar);
  MY_SPARQL_REPORT (sprintf ('Downloading %s: %d bytes',
      full_uri, length (dattext) ) );
  graph_uri := full_uri;
  DELETE FROM RDF_QUAD WHERE G = DB.DBA.RDF_MAKE_IID_OF_QNAME (graph_uri);
  DB.DBA.RDF_LOAD_RDFXML_MT (dattext, full_uri, graph_uri);
  return graph_uri;
err_rep:
  result (sprintf ('%s: %s', __SQL_STATE, __SQL_MESSAGE));
  return graph_uri;
}
;

Done. -- 0 msec.

SQL>create procedure MY_SPARQL_REPORT(in strg varchar)
{
  if (__tag(strg) <> 182)
    strg := cast (strg as varchar) || sprintf (' -- not a string, tag=%d', __tag(strg));
  strg := replace (strg, 'SPARQL_DAV_DATA_URI()', '\044{SPARQL_DAV_DATA_URI()}');
  strg := replace (strg, 'SPARQL_DAV_DATA_PATH()', '\044{SPARQL_DAV_DATA_PATH()}');
  strg := replace (strg, 'SPARQL_FILE_DATA_ROOT()', '\044{SPARQL_FILE_DATA_ROOT()}');
  result (strg);
}
;
```

```
Done. -- 0 msec.

SQL> MY_LOAD_FILE('http://www.w3.org/People/Berners-Lee/card');
REPORT
VARCHAR
_______________________________________________________________________________

..........
```

Using RDF_TTL2HASH

The DB.DBA.RDF_TTL2HASH() does not load TTL content, instead it returns a dictionary of triples in 'long valmode'.

```
create function DB.DBA.RDF_TTL2HASH (
    in strg any,
    in base varchar,
    in graph varchar ) returns any
```

Parameter *flags* is useful when the syntax of the resource is TURTLE-like, but not correct TURTLE. By default, use zero value. Add 1 to let string literals contain end-of-line characters. Add 2 to suppress error messages on blank node verbs. Add 4 to allow variables instead of blank nodes. Add 8 to silently skip triples with literal subjects.

Using RDF_LOAD_RDFXML

The DB.DBA.RDF_LOAD_RDFXML() procedure parses RDF/XML and places its triples into DB.DBA.RDF_QUAD.

```
create procedure DB.DBA.RDF_LOAD_RDFXML (
    in strg any,           -- text of and XML document
    in base_iri varchar,   -- base IRI to resolve relative IRIs
    in graph_iri varchar ) -- the IRI of destination graph
```

See example .

Using RDF_QUAD_URI, RDF_QUAD_URI_L and RDF_QUAD_URI_L_TYPED

To insert a single quad into DB.DBA.RDF_QUAD() table, use one of these procedures:

```
-- Simple insertion of a quad where the object is a node
create procedure DB.DBA.RDF_QUAD_URI (
  in g_uri varchar, in s_uri varchar, in p_uri varchar,
  in o_uri varchar ) -- IRI string or IRI_ID
```

```
-- Simple insertion of a quad where the object is a literal value in 'SQL valmode'
create procedure DB.DBA.RDF_QUAD_URI_L (
  in g_uri varchar, in s_uri varchar, in p_uri varchar,
  in o_lit any ) -- string, number or datetime, NULL is not allowed

create procedure DB.DBA.RDF_QUAD_URI_L_TYPED (
  in g_uri varchar, in s_uri varchar, in p_uri varchar,
  in o_lit any,     -- string value of the literal
  in dt any,        -- datatype as IRI string or IRI_ID, can be NULL
  in lang varchar ) -- language as string or NULL
```

Arguments g_uri, s_uri and p_uri of these three functions should be IRI strings or IRI_IDs. All string arguments should be in UTF-8 encoding, otherwise they will be stored but are not queryable via SPARQL.

Data Export

These two procedures serialize a vector of triples into a session, in TURTLE or RDF/XML syntax. In their current versions, every triple is printed in a separate top-level record (say, in an rdf:Description tag), without any pretty-printing or nesting optimization.

```
create procedure DB.DBA.RDF_TRIPLES_TO_TTL (
    inout triples any, -- vector of triples in 'long valmode'.
    inout ses any )    -- an output stream in server default encoding

create procedure DB.DBA.RDF_TRIPLES_TO_RDF_XML_TEXT (
    inout triples any,          -- vector of triples in 'long valmode'.
    in print_top_level integer, -- zero if only rdf:Description tags should be written,
                                -- non-zero if the rdf:RDF top-level element should also be written
    inout ses any )             -- an output stream in server default encoding
```

Data query

```
-- Local execution of SPARQL via SPARQL protocol, produces a result set of SQL values.
create procedure DB.DBA.SPARQL_EVAL (
    in query varchar,      -- text of SPARQL query to execute
    in dflt_graph varchar, -- default graph IRI, if not NULL then this overrides what's specified in quer
    in maxrows integer )   -- limit on numbers of rows that should be returned.

-- Similar to SPARQL_EVAL, but returns a vector of vectors of SQL values.
create function DB.DBA.SPARQL_EVAL_TO_ARRAY (
    in query varchar,      -- text of SPARQL query to execute
    in dflt_graph varchar, -- default graph IRI, if not NULL then this overrides what's specified in quer
    in maxrows integer )   -- limit on numbers of rows that should be returned.
returns any

-- Remote execution of SPARQL via SPARQL protocol, produces a result set of SQL values.
create procedure DB.DBA.SPARQL_REXEC (
    in service varchar,    -- service URI to call via HTTP
    in query varchar,      -- text of SPARQL query to execute
    in dflt_graph varchar, -- default graph IRI, if not NULL then this overrides what's specified in quer
    in named_graphs any,   -- vector of named graph IRIs, if not NULL then this overrides what's specifie
    in req_hdr any,        -- additional HTTP header lines that should be passed to the service; 'Host: .
    in maxrows integer,    -- limit on numbers of rows that should be returned.
    in bnode_dict any )    -- dictionary of bnode ID references.

-- Similar to SPARQL_REXEC (), but returns a vector of vectors of SQL values.
-- All arguments are the same.
create function DB.DBA.SPARQL_REXEC_TO_ARRAY (
    in service varchar, in query varchar, in dflt_graph varchar, in named_graphs any,
    in req_hdr any, in maxrows integer, in bnode_dict any)
returns any

-- Similar to SPARQL_REXEC (), but fills in output parameters with metadata (like exec metadata) and a ve
s of 'long valmode' values.
-- First seven arguments are the same.
create procedure DB.DBA.SPARQL_REXEC_WITH_META (
    in service varchar, in query varchar, in dflt_graph varchar, in named_graphs any,
    in req_hdr any, in maxrows integer, in bnode_dict any,
    out metadata any,  -- metadata like exec () returns.
    out resultset any) -- results as 'long valmode' value.
```

If the query is a CONSTRUCT or DESCRIBE then the result set consists of a single row and column, the value inside is a dictionary of triples in 'long valmode'.

16.2.7. Useful Internal Functions

Conversion Functions for XMLSchema/RDF Data Serialization Syntax

These functions emulate constructor functions from XQuery Core Function Library.

```
create function DB.DBA."http://www.w3.org/2001/XMLSchema#boolean" (in strg any) returns integer
create function DB.DBA."http://www.w3.org/2001/XMLSchema#dateTime" (in strg any) returns datetime
create function DB.DBA."http://www.w3.org/2001/XMLSchema#double" (in strg varchar) returns double precisi
create function DB.DBA."http://www.w3.org/2001/XMLSchema#float" (in strg varchar) returns float
create function DB.DBA."http://www.w3.org/2001/XMLSchema#integer" (in strg varchar) returns integer
```

RDF-specific Predicates

```
-- Returns 1 if string s matches pattern p, 0 otherwise
create function DB.DBA.RDF_REGEX (
    in s varchar,            -- source string to check
    in p varchar,            -- regular expression pattern string
    in coll varchar := null) -- unused for now (modes are not yet implemented)

-- Returns 1 if language identifier r matches lang pattern t
create function DB.DBA.RDF_LANGMATCHES (
  in r varchar, -- language identifies (string or NULL)
  in t varchar) -- language pattern (exact name, first two letters or '*')
```

16.2.8. Default and Named Graphs

Sometimes the default graph IRI is not known when the SPARQL query is composed. It can be added at the very last moment by providing the IRI in a 'define' clause as follows:

```
define input:default-graph-uri &lt;http://example.com&gt
```

Such a definition overrides the default graph URI set in query by the 'FROM ...' clause (if any).

The query may contain more than one *define input:default-graph-uri* . The set of values of *input:default-graph-uri* has the highest possible priority and cannot be redefined in the rest of the text of the query by FROM clauses.

FROM NAMED clauses can be used multiple times in one query:

```
SPARQL
  SELECT ?id
  FROM NAMED <http://example.com/user1.ttl>
  OPTION (get:soft "soft", get:method "GET")
  FROM NAMED <http://example.com/user2.ttl>
  OPTION (get:soft "soft", get:method "GET")
  WHERE { GRAPH ?g { ?id a ?o } }
```

Similarly, *define input:named-graph-uri <http://example.com>* is a replacement for a FROM NAMED clause

When Virtuoso receives a SPARQL request via HTTP, the value of the default graph can be set in the protocol using a *default-graph-uri* HTTP parameter. Multiple occurrences of this parameter are allowed. This HTTP parameter is converted into *define input:default-graph-uri* . There's similar support for *named-graph-uri* HTTP parameter. For debugging purposes, graph names set in the protocol are sent back in the reply header as *X-SPARQL-default-graph: ...* and *X-SPARQL-named-graph: ...* header lines, one line per graph.

A web service endpoint may provide different default configurations for different host names mentioned in HTTP requests. This facility is configured via table *DB.DBA.SYS_SPARQL_HOST* .

```
create table DB.DBA.SYS_SPARQL_HOST (
  SH_HOST       varchar not null primary key, -- host mask
  SH_GRAPH_URI varchar,                 -- default graph uri
  SH_USER_URI   varchar,                  -- reserved for any use in applications
```

```
  SH_BASE_URI varchar,                  -- for future use (not used currently) to set BASE in sparql quer
  SH_DEFINES long varchar,              -- additional defines for requests
  PRIMARY KEY (SH_HOST)
)
```

When the SPARQL web service endpoint receives a request it checks the *Host* HTTP header line. This line contains zero or more target host names, delimited by commas. For every host name in the line, the service scans the *DB.DBA.SYS_SPARQL_HOST* table in search of a row containing a matching host name in *SH_HOST* . The *SH_HOST* field acts as 'pattern' argument for the SQL string operator LIKE. If a matching row is found, the text of SPARQL request is extended.

If a default graph is not explicitly set by the HTTP parameters and *SH_GRAPH_URI* is not null then the default graph is set to *SH_GRAPH_URI* .

If *SH_DEFINES* is not null then it is added in front of the query; so this field is a good place for the text for any DEFINE options. See various DEFINE examples usage.

SH_USER_URI is for arbitrary user data and can be used in any way by the application that is "responsible" for the declared host.

The search of *DB.DBA.SYS_SPARQL_HOST* stops at the first found row, other possible matches are silently ignored.

Example Usage:

```
INSERT INTO DB.DBA.SYS_SPARQL_HOST (SH_HOST, SH_GRAPH_URI, SH_USER_URI, SH_BASE_URI, SH_DEFINES) VALUES
('example.com', 'urn:example:com', 'urn:example:user', NULL, 'define input:inference "http://mygraph.com"
```

16.2.9. Calling SQL from SPARQL

A SPARQL expression can contain calls to Virtuoso/PL functions and built-in SQL functions in both the WHERE clause and in the result set. Two namespace prefixes, *bif* and *sql* are reserved for these purposes. When a function name starts with the *bif:* namespace prefix, the rest of the name is treated as the name of a SQL BIF (Built-In Function). When a function name starts with the *sql:* namespace prefix, the rest of the name is treated as the name of a Virtuoso/PL function owned by DBA with database qualifier DB, e.g. *sql:example(...)* is converted into *DB.DBA."example"(...)* .

In both cases, the function receives arguments in SQL format ('SQL valmode') and also returns the result in SQL format. The SPARQL compiler will automatically add code for format conversion into the resulting SQL code so SQL functions can be used even if *define output:valmode 'LONG'* forces the use of RDF representation in the result set.

Example with sql: namespace prefix

```
SQL>create procedure DB.DBA.ComposeInfo (
  in pname varchar,

16.2.10. SPARQL DESCRIBE

The SPARQL specification does not define the precise output of DESCRIBE, so different applications may need different results for the same subject. Some applications need quick generation of short and incomplete results whereas others may need detailed reports composed from multiple sources.

The supported option values for *sql:describe-mode* are:

- *(default)*

  -- for subject-predicate-object triples of given IRI as subject plus subject-predicate-object triples of given IRI as object. No "sql:describe-mode" or define sql:describe-mode "" will set default.
- *SPO*

  -- for subject-predicate-object triples of given IRI as subject;
- *CBD*

  -- for concise bound description of given subject (i.e., SPO + CBD of each blank node object found by SPO, recursively);
- *OBJCBD*

  -- like CBD but traverses from objects to subjects, not from subjects to objects;
- In addition, user may write his/her own "postporocessing" function that will get the result of describe, lists of "good" and "bad" graphs, name of storage, options and alter it in any way he/she wishes. The notation is e.g. define sql:describe-mode "SPO+XYZ", meaning SPO describe and call DB.DBA.SPARQL_DESC_POSTPROC_XYZ on top of it. See below example usage.

If define *sql:describe-mode "xxx"* is specified then the generated SQL code will use the procedures named:

```
DB.DBA.SPARQL_DESC_DICT_xxx (in subj_dict any, in consts any, in graphs
any, in storage_name any, in options any)
```

and

```
DB.DBA.SPARQL_DESC_DICT_xxx_PHYSICAL (in subj_dict any, in consts any,
in graphs any, in storage_name any, in options any)
```

In a new blank database, only two such pairs of procedures are created. Procedures *DB.DBA.SPARQL_DESC_DICT_SPO* and *DB.DBA.SPARQL_DESC_DICT_SPO_PHYSICAL* are for *sql:describe-mode "SPO"* . This pair of procedures searches for all triples where the input IRIs are used as subjects; they are faster than the default routine which searches for all triples where the input IRIs are used as subjects or objects. Similarly, *DB.DBA.SPARQL_DESC_DICT_CBD* and *DB.DBA.SPARQL_DESC_DICT_CBD_PHYSICAL* are for *sql:describe-mode "CBD"* . CBD stands for Concise Bounded Description of given subject (i.e., SPO + CBD of each blank node object found by SPO, recursively).

In each pair, both procedures have the same semantics but the second one is used if and only if the SPARQL compiler can prove that all subjects to process are from physical storage *(DB.DBA.RDF_QUAD)* . Thus the second procedure will not search for subjects in Linked Data Views.

Each procedure should return a dictionary with triples as keys and integer 1 as values. So the dictionary is filled by calls like:

```
dict_put (resulting_dict,
          vector (subj_iri_id, pred_iri_id, obj_iri_id_or_rdf_box),
          1);
```

Procedure arguments are as follows:

- *subj_dict*

  - a dictionary whose keys are IRI IDs and maybe values of other types, esp. RDF boxes. Keys are subjects to be described, so values other than IRI IDs should usually be ignored. Values should be ignored.
- *consts*

- a vector of IRI IDs and values of other types. The items contained in the vector are subjects to be described, as with the keys of subj_dict.

- *graphs*

  - a vector of IRI IDs of graphs that can be used for DESCRIBE. The vector may contain garbage, like in the two previous cases. A NULL can be passed instead of a vector indicating that the source graphs are not specified in the source query.

- *storage_name*

  - the value of "define input:storage" from the original SPARQL query, NULL if missing.

- *options*

  - reserved for future use and can be ignored.

One should grant execute permission on both procedures to SPARQL_SELECT before referring to them in SPARQL.

SPARQL DESCRIBE Examples

Assume the following statements are executed:

```
__rdf_set_bnode_t_treshold();
SET blobs ON;
SET echo ON;

SPARQL PREFIX xmp: <http://example.com/xmp/>
CLEAR GRAPH xmp:good1;

```

16.2.11. Transitivity in SPARQL

Virtuoso SPARQL allows access to Virtuoso's SQL transitivity extension. Read the SQL section for a definition of the options.

The SPARQL syntax is slightly different from the SQL, although the option names and meanings are the same.

In SPARQL, the transitive options occur after a subquery enclosed in braces:

The below produces all the IRI's that are the same as <http://dbpedia.org/resource/New_York>.

```
SPARQL
SELECT ?syn
WHERE
  {
    {
      SELECT ?x ?syn
      WHERE
        {
          { ?x owl:sameAs ?syn }
          UNION
          { ?syn owl:sameAs ?x }
```

```
        }
      }
      OPTION ( TRANSITIVE, t_in (?x), t_out (?syn), t_distinct, t_min (0) )
      FILTER (?x = <http://dbpedia.org/resource/New_York>) .
    }
```

In this case, we provide a binding for ?x in the filter outside of the transitive subquery. The subquery therefore is made to run from in to out. The same effect would be accomplished if we bound ?syn and SELECT ?x, the designations of in and out are arbitrary and for transitive steps that can be evaluated equally well in both directions this makes no difference.

The transitive subquery in the above is

```
{SELECT ?syn
 WHERE
  {
    { SELECT ?x ?syn
      WHERE
       {
         { ?x owl:sameAs ?syn }
         UNION
         { ?syn owl:sameAs ?x}
       }
    } OPTION (TRANSITIVE, t_in (?x), t_out (?syn), t_distinct, t_min (0) )
  }
} .
```

Leaving out the option would just look for one step of owl:sameAs. Making it transitive will apply the subquery to all bindings it produces until all are visited at least once (the t_distinct modifier).

If the transitive step consists of a single triple pattern, there is a shorthand:

```
<alice> foaf:knows ?friend option (transitive t_min (1))
```

will bind ?friend to all directly and indirectly found foaf:known individuals. If t_min had been 0, Malice> would have also been in the generated bindings.

The syntax is

```
option (transitive transitivity_option[,...])

transitivity_option ::=  t_in (<variable_list>)
| t_out (<variable_list>)
| t_distinct
| t_shortest_only
| t_no_cycles
| t_cycles_only
| t_min (INTNUM)
| t_max (INTNUM)
| t_end_flag (<variable>)
| t_step (<variiable_or_step>)
| t_direction INTNUM

variable_list ::= <variable> [,...]

variable_or_step ::= <variable> | path_id' | 'step_no'
```

Unlike SQL, variable names are used instead of column numbers. Otherwise all the options have the same meaning.

Some examples of the use of transitivity are:

Collection of Transitivity Option Demo Queries for SPARQL

Example for finding out what graphs contain owl:sameAs for "New York"

To find out what graphs contain owl:sameAs for Dan York, we do

```
SELECT ?g ?x count (*) as ?count
WHERE {
        {
          SELECT ?x ?alias ?g
          WHERE {
                  {
                    GRAPH ?g {?x owl:sameAs ?alias }
                  }
          UNION
                  {
                   GRAPH ?g {?alias owl:sameAs ?x}
                  }
                }
        }
        OPTION ( TRANSITIVE,
                 t_in (?x),
                 t_out (?alias),
                 t_distinct,
                 t_min (1)) .
        FILTER (?x = <http://dbpedia.org/resource/New_York> ) .
      }
```

Here we select all paths that start with the initial URI and pass through one or more sameAs statements. Each step produces a result of the transitive subquery. The graph where the sameAs triple was found is returned and used as the grouping column. In this way we see how many times each graph is used. Note that graphs are counted many times since the graphs containing immediate sameAs statements are counted for paths of length 1, then again as steps on paths that reach to their aliases and so on.

Example for query that takes all the people known by Tim Berners-Lee, to a depth between 1 and 4 applications of the subquery

This query takes all the people known by kidehen, to a depth between 1 and 4 applications of the subquery. It then sorts them by the distance and the descending count of connections of each found connection. This is equivalent to the default connections list shown by LinkedIn.

```
SPARQL
SELECT ?o ?dist ((SELECT COUNT (*) WHERE {?o foaf:knows ?xx}))
WHERE
  {
    {
      SELECT ?s ?o
      WHERE
        {
          ?s foaf:knows ?o
        }
    } OPTION ( TRANSITIVE,
               t_distinct,
               t_in(?s),
               t_out(?o),
               t_min (1),
               t_max (4),
               t_step ('step_no') as ?dist ) .
    FILTER (?s= <http://www.w3.org/People/Berners-Lee/card#i>)
  }
ORDER BY ?dist DESC 3
LIMIT 50
```

Example for query that takes all the people known by Tim Berners-Lee, to a depth between 2 and 4 applications of the subquery

This query takes all the people known by kidehen, to a depth between 2 and 4 applications of the subquery. It then sorts them by the distance and the descending count of connections of each found connection. This is equivalent to the default connections list shown by LinkedIn.

```
SPARQL
SELECT ?o ?dist ((SELECT COUNT (*) WHERE {?o foaf:knows ?xx}))
```

```
WHERE
  {
    {
      SELECT ?s ?o
      WHERE
        {
          ?s foaf:knows ?o
        }
    } OPTION ( TRANSITIVE,
               t_distinct,
               t_in(?s),
               t_out(?o),
               t_min (2),
               t_max (4),
               t_step ('step_no') as ?dist) .
    FILTER (?s= <http://www.w3.org/People/Berners-Lee/card#i>)
  }
ORDER BY ?dist DESC 3
LIMIT 50
```

Example for finding how two people know each other and what graphs are involved in the connection

To find how two people know each other and what graphs are involved in the connection, we do:

```
SPARQL
SELECT ?link ?g ?step ?path
WHERE
  {
    {
      SELECT ?s ?o ?g
      WHERE
        {
          graph ?g {?s foaf:knows ?o }
        }
    } OPTION ( TRANSITIVE,
               t_distinct,
               t_in(?s),
               t_out(?o),
               t_no_cycles,
               T_shortest_only,
               t_step (?s) as ?link,
               t_step ('path_id') as ?path,
               t_step ('step_no') as ?step,
               t_direction 3) .
    FILTER (?s= <http://www.w3.org/People/Berners-Lee/card#i>
    && ?o = <http://www.advogato.org/person/mparaz/foaf.rdf#me>)
  }
  LIMIT 20
```

This query binds both the t_in and t_out variables. The ?g is left as a free variable. Also, specifying ?s and the system defined constants step_no and path_id as with t_step, we get for each transitive step a row of results with the intermediate binding of ?s, the count of steps from the initial ?s and a distinct identifier for the individual path, since there can be many distinct paths that link the ?s and ?o specified in the filter.

See the SQL transitive option section for details on the meaning of step_no and path_id.

Example for TBox Subsumption

Subsumption Demo Using Transitivity Clause

Yago Class Hierarchy (TBox) Subsumption

AlphaReceptors

```
# all subjects with IRI: <http://dbpedia.org/class/yago/AlphaReceptor105609111>,
# that are sub-classes of anything (hence ?y)
# without restrictions on tree levels
SELECT ?y
```

```
FROM <http://dbpedia.org/resource/classes/yago#>
WHERE
  {
    {
      SELECT *
      WHERE
        {
          ?x rdfs:subClassOf ?y .
        }
    }
    OPTION (TRANSITIVE, t_distinct, t_in (?x), t_out (?y) ) .
    FILTER (?x = <http://dbpedia.org/class/yago/AlphaReceptor105609111>)
  }
```

Example for Receptors

```
SELECT ?x
FROM <http://dbpedia.org/resource/classes/yago#>
WHERE
  {
    {
      SELECT *
      WHERE
        {
          ?x rdfs:subClassOf ?y .
        }
    } OPTION (transitive, t_distinct, t_in (?x), t_out (?y) ) .
  FILTER (?y = <http://dbpedia.org/class/yago/Receptor105608868>)
}
```

Inference Rule example using transitive properties from SKOS vocabulary

The following example demostrates the steps how to retrieve the skos ontology, add triples for skos:broaderTransitiveinto the graph, define inference rule, and at the and execute sparql query with inference rule and transitivity option. The queries were executed against the LOD instance (http://lod.openlinksw.com):

1. Make the Context graph, assuming you don't want to load entire SKOS vocabulary into our Quad Store:

```
SQL>SPARQL
PREFIX skos: <http://www.w3.org/2004/02/skos/core#>
PREFIX rdfs: <http://www.w3.org/2000/01/rdf-schema#>
INSERT INTO GRAPH <urn:rules.skos> { skos:broader rdfs:subPropertyOf skos:broaderTransitive .
                                     skos:narrower rdfs:subPropertyOf skos:narrowerTransitive };
```

2. OR Load entire SKOS ontology into Quad Store via iSQL interface (commandline or HTML based Conductor):

```
SQL>DB.DBA.RDF_LOAD_RDFXML (http_get ('http://www.w3.org/2009/08/skos-reference/skos-owl1-dl.rdf')
Done.
```

3. Make Context Rule:

```
SQL>rdfs_rule_set ('skos-trans', 'urn:rules.skos');
Done.
```

4. Go to SPARQL endpoint, for ex. http://lod.openlinksw.com/sparql
5. Use inference rule pragma to set context rule for SPARQL query, i.e:

```
SPARQL
DEFINE input:inference "skos-trans"
PREFIX p: <http://dbpedia.org/property/>
PREFIX dbpedia: <http://dbpedia.org/resource/>
PREFIX category: <http://dbpedia.org/resource/Category:>
PREFIX rdfs: <http://www.w3.org/2000/01/rdf-schema#>
PREFIX skos: <http://www.w3.org/2004/02/skos/core#>
PREFIX geo: <http://www.georss.org/georss/>

SELECT DISTINCT ?m ?n ?p ?d
WHERE
  {
    ?m rdfs:label ?n.
    ?m skos:subject ?c.
    ?c skos:broaderTransitive category:Churches_in_Paris OPTION (TRANSITIVE) .
    ?m p:abstract ?d.
```

```
    ?m geo:point ?p
    FILTER ( lang(?n) = "fr" )
    FILTER ( lang(?d) = "fr" )
  }
```

6. You will get 22 rows returned from the query. Note that for comparison, if the option (transitive) is ommitted, then only 2 rows will be returned in our example query:

Figure 16.42. Transitive option

m	n	p	d
http://dbpedia.org/resource/Basilique_Saint-Denis	Basilique Saint-Denis	48.9355555556 2.35972222222	La basilique Saint-Denis est une église de style gothique située à Saint-Denis, en Seine-Saint-Denis (93). Elle a le statut de cathédrale depuis 1966, mais elle est aussi une abbatiale.
http://dbpedia.org/resource/Saint-Julien-le-Pauvre	Église Saint-Julien-le-Pauvre	48.8520833333 2.34708333333	L'église Saint-Julien-le-Pauvre est l'église grecque-melkite catholique de Paris, située rive gauche d le quartier latin, proche de la Seine. Batie en 975 par ordre d'Henri Ier. Eglise Saint-Julien-le-Pauv Julien-le-Pauvre Eglise
http://dbpedia.org/resource/%C3%89glise_de_la_Ste.-Trinit%C3%A9%2C_Paris	Église de la Sainte-Trinité de Paris	48.8772222222 2.33138888889	L'église de la Sainte-Trinité, dans le 9e arrondissement de Paris, est située place d'Estienne-d'Orve au départ de la rue Blanche, dans le prolongement de la rue Saint-Lazare et de la rue de la Chauss d'Antin (elle était conçue pour être vue depuis l'Opéra).
http://dbpedia.org/resource/Saint-Nicolas-du-Chardonnet	Église Saint-Nicolas-du-Chardonnet	48.8491666667 2.35027777778	L'église Saint-Nicolas-du-Chardonnet est située à Paris, 23, rue des Bernardins, dans le V arrondissement, dans le quartier Saint-Victor, à côté de la Maison de la Mutualité. Depuis le 27 février 1977, date de son occupation par la force par des proches de la Fraternité sacerdotale Saint-Pie-X dont elle dépend officieusement depuis, elle constitue le principal lieu de culte parisien mouvement catholique traditionaliste — parfois qualifié d'« intégrisme » — ainsi que, dans une certaine mesure, de la frange catholique de l'extrême droite française.
http://dbpedia.org/resource/Saint-%C3%89tienne-du-Mont	Église Saint-Étienne-du-Mont	48.8466666667 2.34805555556	L'église Saint-Étienne-du-Mont est une église située sur la montagne Sainte-Geneviève, dans le V arrondissement de Paris, à proximité du lycée Henri-IV et du Panthéon.
http://dbpedia.org/resource/Saint-S%C3%A9verin_%28Paris%29	Église Saint-Séverin	48.8520388889 2.34567222222	L'église Saint-Séverin est une petite église du Quartier Latin de Paris, dans le quartier de Saint-Séverin . C'est la plus ancienne église située sur la rive gauche de Paris. L'ensemble formé par l'ég la « maison paroissiale - presbytère », le square André-Lefèbvre et le cloître est délimité par la rue des Prêtres-Saint-Séverin, la rue de la Parcheminerie, la rue Saint-Jacques et la rue Saint-Séverin. est utilisée comme lieu de culte de la paroisse Saint-Séverin-Saint-Nicolas. En effet, depuis 1977, de l'occupation de l'église Saint-Nicolas-du-Chardonnet par des fidèles de la Fraternité sacerdotale Saint-Pie-X, le territoire de Saint-Nicolas dépend également de Saint-Séverin. La paroisse a recouv l'usage d'un immeuble sis 39, boulevard Saint-Germain, à proximité de Saint-Nicolas.
http://dbpedia.org/resource/Piti%C3%A9-Salp%C3%AAtri%C3%A8re_Hospital	Hôpital de la Salpêtrière	48.837 2.365	L'hôpital de la Salpêtrière est un hôpital de l'Assistance publique - hôpitaux de Paris (AP-HP) situé dans le 13 arrondissement de Paris.
http://dbpedia.org/resource/Abbey_of_Saint-Germain-des-Pr%C3%A9s	Abbaye de Saint-Germain-des-Prés	48.8538888889 2.33444444444	L'abbaye de Saint-Germain-des-Prés était la plus ancienne et la plus prestigieuse abbaye de Paris, située dans le quartier de Saint-Germain dans le 6e arrondissement de Paris. Elle fut supprimée à l Révolution. Son abbatiale sert depuis le Concordat d'église paroissiale.
http://dbpedia.org/resource/%C3%89glise_Saint-Sulpice%2C_Paris	Église Saint-Sulpice (Paris)	48.8511111111 2.33472222222	L'église Saint-Sulpice est une grande église de Paris, située dans le VI arrondissement.

Inference Rule example using transitive properties from SKOS vocabulary: Variant II

This example shows how to find entities that are subcategories of Protestant Churches, no deeper than 3 levels within the concept scheme hierarchy, filtered by a specific subcategory. It demonstrates use of inference rules, sub-queries, and filter to obtain entities associated with category: Protestant_churches combined with the use of the transitivitve closure, sets to a maximum of 3 steps down a SKOS based concept scheme hierarchy:

1. Make sure the inference rule "skos-trans" is created as described in the previous example
2. Go to SPARQL endpoint, for ex. http://lod.openlinksw.com/sparql
3. Use inference rule pragma to set context rule for SPARQL query, i.e:

```
DEFINE input:inference "skos-trans"
PREFIX p: <http://dbpedia.org/property/>
PREFIX dbpedia: <http://dbpedia.org/resource/>
PREFIX category: <http://dbpedia.org/resource/Category:>
PREFIX rdfs: <http://www.w3.org/2000/01/rdf-schema#>
PREFIX skos: <http://www.w3.org/2004/02/skos/core#>
PREFIX geo: <http://www.georss.org/georss/>

SELECT DISTINCT ?c AS ?skos_broader
       ?trans AS ?skos_narrower
       ?dist AS ?skos_level
       ?m ?n ?p AS ?geo_point
WHERE
```

```
{
  {
    SELECT ?c  ?m ?n ?p ?trans ?dist
    WHERE
      {
            ?m rdfs:label ?n.
            ?m skos:subject ?c.
            ?c skos:broaderTransitive category:Protestant_churches .
            ?c skos:broaderTransitive ?trans
              OPTION ( TRANSITIVE,
                       t_distinct,
                       t_in (?c),
                       t_out (?trans),
                       t_max (3),
                       t_step ( 'step_no' ) as ?dist ) .
            ?m p:abstract ?d.
            ?m geo:point ?p
            FILTER ( lang(?n) = "en" )
            FILTER ( lang(?d) = "en" )
      }
  }
  FILTER ( ?trans = <http://dbpedia.org/resource/Category:Churches_in_London> )
}
ORDER BY ASC (?dist)
```

4. You will get 22 rows returned from the query.

16.2.12. Supported SPARQL-BI "define" pragmas

SPARQL-BI compiler and run-time support are not isolated from environment and some used heuristics are not perfect and sometimes different use cases require different behavior within same standard. These reasons are seen frequently in the industry, and the solution is well known: compiler pragmas. So we allow them at the beginning of any SPARQL query in form:

```
define QName value
```

Pragmas to control the input data set for the query

```
input:default-graph-uri works like "FROM" clause;
input:named-graph-uri works like "FROM NAMED" clause;
input:default-graph-exclude works like "NOT FROM" clause;
input:named-graph-exclude works like "NOT FROM NAMED" clause.
```

The difference is that these pragmas have higher priority and they can be used for security restrictions in combination with `define input:freeze` that blocks further changes in the list of source graphs. The web service endpoint (or similar non-web application) can edit the incoming query by placing list of pragmas ended with `input:freeze` in front of query text. Even if the intruder will try to place some graph names, it will get compilation error, not an access to the data. input:freeze disables all `input:grab-...` pragmas as well.

- `input:ifp` : adds IFP keyword in OPTION (QUIETCAST, ...) clause in the generated SQL. The value of this define is not used ATM, an empty string is safe for future extensions.
- `input:same-as` : works like input:ifp but adds SAME_AS keyword.
- `input:storage` : selects quad map storage to use. The value is an IRI of storage, the default value is, of course, virtrdf:DefaultQuadStorage. If the value is an empty string then only quads from RDF_VIEW are used. This is a good choice for low-level admin procedures, for two reasons: they will not interfere with any changes in virtrdf:DefaultQuadStorage and they will continue to work even if all compiler's metadata are corrupted, including the description of virtrdf:DefaultQuadStorage (define input:storage "" switches the SPARQL compiler to a small set of metadata that are built in server C code and thus are very hard to corrupt by users).
- `input:inference` : specifies the name of inference rule set to use.
- `input:param (and synonyms input:params, sql:param, sql:params)` : declares a variable name as a protocol parameter. The SPARQL query can refer to protocol parameter X via variable with special syntax of name ?::X . If a query text should be made by query builder that does not understand SPARQL-BI extensions then the text may contain variable ?X and define input:param "X" . This does not work for positional parameters, one can not replace a reference to ?::3 with ?3 and define input:param "3".
- `input:grab-var` : Network Resource Fetch values of variable;
- `input:grab-iri` : Network Resource Fetch the constant IRI;
- `input:grab-all` : Network Resource Fetch all constants and variables of the query;
- `input:grab-seealso (and synonym input:grab-follow-predicate)` : sets predicate that tells where to Fetch more Network Resource data about a subject;
- `input:grab-limit` : how many resources can be fetched;
- `input:grab-depth` : how many iterations can be done, sponging additional data on each iteration;
- `input:grab-base` : base to resolve relative IRIs before passing to Sponger;
- `input:grab-resolver` : IRI resolving procedure (i.e., one that turns base and relative IRI to an absolute IRI);
- `input:grab-destination` : single resource that should be filled in with results of all fetchings;
- `input:grab-loader` : a name of procedure that retrieve the resource via HTTP, parse it and store it.

All these pragmas are described in more details here , but in addition there are some experimental:

- `input:grab-intermediate` : extends the set of IRIs to sponge, useful in combination with input:grab-seealso. If present then for a given subject, Network Resource Fetch will retrieve not only values of see-also predicates for that subject but the subject itself. The define value is not used in current implementation.
- `input:grab-group-destination` : resembles input:grab-destination but sponges will create individual graphs for Network Resource Fetch results, and in additional to this common routine, a copy of each Network Resource Fetch result is added to the resource specified by the value of input:grab-group-destination. input:grab-destination redirects loadings, input:grab-group-destination duplicates them.
- `get:soft` : "soft" or "replacing", depending on mode of loading source graph;
- `get:uri` : an URI of web resource where the graph should come from (e.g., a local mirror);
- `get:method` : "GET" or "MGET", depending on loading the resource itself or loading metadata about the resource;
- `get:refresh` : limits the lifetime of a local cached copy of the source, the value is in seconds. Should be used in combination with get:soft;

- `get:proxy` : the proxy server to use, as "host:port" string.

These defines are described also here . Note that all of them can be used in option list of "FROM ... OPTION (get:...)" extended SPARQL-BI syntax for FROM/FROM NAMED clause.

Note that all of them can be used in option list of "FROM ... OPTION (get:...)" extended SPARQL-BI syntax for FROM/FROM NAMED clause.

Pragmas to control code generation

- `sql:assert-user` : defines the user who is supposed to be the single "proper" use for the query. If the compiler is launched by other user, an error is signaled. The typical use is define sql:assist-user "dba". This is too weak to be a security measure, but may help in debugging of security issues.
- `sql:gs-app-callback` : application-specific callback that returns permission bits of a given graph;
- `sql:gs-app-uid` : application-specific user id to use in callback.

See Also:

RDF Graph Security

- `sql:globals-mode` : tells how to print names of global variables, supported values are "XSLT" (print colon before name of global variable and "SQL" (print as usual).
- `sql:log-enable` : value that will be passed to SPARUL procedures and there it will be passed to log_enable() BIF. Thus define sql:log-enable N will result in log_enable(N, 1) at the beginning of the operation and other log_enable() call will restore previous mode of transaction log at exit from the procedure or at any error signalled from it.
- `sql:table-option` : value will be added as an option to each triple in the query and later it will be printed in TABLE OPTION (...) clause of source table clause. This works only for SQL code for plain triples from RDF_QUAD, fragments of queries related to RDF Views will remain unchanged.
- `sql:select-option` : value will be added as an global OPTION () clause of the generated SQL SELECT. This clause is always printed, it is always at least OPTION (QUIETCAST, ...). The most popular use case is define sql:table-option "ORDER" to tell the SQL compiler execute joins in the order of their use in the query (this can make query compilation much faster but the compilation result can be terrible if you do not know precisely what you're doing and not inspected execution plan of the generated SQL query).
- `sql:describe-mode` : sets procedures that will produce the result of a DESCRIBE query. The pragma is ignored for other types of SPARQL queries. In the default mode, the result contains all X ?p ?o and all ?s ?p X triples for each given X. In "SPO" mode, the result contains X ?p ?o triples only. In "CBD" mode, the result contains concise bound descriptions of given subjects. Application developers may add more modes.
- `sql:signal-void-variables` : the most useful debugging variable if Linked Data Views are in use. It tells the SPARQL compiler to signal an error if it can prove that some variable can never be bound. Usually it means error in query, like typo in IRI or totally wrong triple pattern.

Pragmas to control the type of the result

- `output:valmode` : tells the compiler which SQL datatypes should be used for output values. ODBC clients and the like known nothing about RDF and expect plain SQL values, so the appropriate value for them is "SQLVAL" and that's the default. When a Virtuoso/PL procedure is RDF-aware and keeps results for further passing to other SPARQL queries or some low-level RDF routines, the value "LONG" tells the compiler to preserve RDF boxes as is and to return IRI IDs instead of IRI string value. Third possible value, "AUTO", is for dirty hackers that do not want any conversion of any sort at the output to read the SQL output of SPARQL front-end, find the format of each column and add the needed conversions later. You will probably never need it.
- `output:format` : tells the compiler that the query should produce a string output with the serialization of the result, not a result set. There are three of them because the caller, like SPARQL web service endpoint, may not know the actual type of the query that should be executed. The value of output:format is used for SELECT and data manipulation queries, if specified, it can also be used for CONSTRUCT, DESCRIBE or ASK, if it is specified but related output:dict-format or output:scalar-format is not.
- `output:scalar-format` : tells the compiler that the query should produce a string output with the serialization of the result, not a result set. There are three of them because the caller, like SPARQL web service endpoint, may not know the actual type of the query that should be executed. The value of output:scalar-format is used for ASK queries only, if specified.
- `output:dict-format` : tells the compiler that the query should produce a string output with the serialization of the result, not a result set. There are three of them because the caller, like SPARQL web service endpoint, may not know the actual type of the query that should be executed. The value of output:dict-format is used for CONSTRUCT and

DESCRIBE queries only, if specified.

Supported formats that return a string session

- "RDF/XML",
- "TURTLE" (and "TTL" is a synonym),
- "JSON" (canonical JSON for result sets, Talis-style JSON for CONSTRUCT and DESCRIBE),
- "JSON;ODATA" (oData-style JSON for CONSTRUCT and DESCRIBE, error otherwise),
- "RDFA;XHTML" (only for CONSTRUCT and DESCRIBE, error otherwise),
- "ATOM;XML" (only for CONSTRUCT and DESCRIBE as well).

Supported formats that do not return a string session to the caller

Supported formats that do not return a string session to the caller, but form an HTTP response instead and send it directly to the client HTTP connection with an appropriate HTTP header:

- "HTTP+XML mime/type",
- "HTTP+TTL mime/type",
- "HTTP+NT mime/type". A MIME type in value will be placed in the returned header, it should be separated from the starting keyword with one white space.

Supported Special formats

A special format "_JAVA_" is for SPARQL queries sent via JDBC. It changes only the output of ASK queries.

The "_JAVA_" and "_UDBC_" are aliases in Virtuoso Version 6.1.5. Till Virtuoso 6.1.5 the default behaves as "TTL". For Virtuoso version 6.1.5 and higher it is ODBC/JDBC oriented e.g. "_UDBC_" is the default format for ODBC/JDBC clients.

Note : If you want to revert to old TTL behaviour, you should specify it explicitly via:

```
define output:format "TTL"
```

Note: Pragmas output:valmode and output:format may conflict if used together, and if they're not in conflict then output:valmode is redundant: the compiler knows for sure which output:valmode-s are needed by various output:format-s.

- `output:route` : works only for SPARUL operators and tells the SPARQL compiler to generate procedure names that differ from default. As a result, the effect of operator will depend on application. That is for tricks. E.g., consider an application that extracts metadata from DAV resources stored in the Virtuoso and put them to RDF storage to make visible from outside. When a web application has permissions and credentials to execute a SPARUL query, the changed metadata can be written to the DAV resource (and after that the trigger will update them in the RDF storage), transparently for all other parts of application.
- `output:maxrows` : limits the number of rows in the returned result set. The integer value is expected, the positive integer value is obviously recommended.

Minor notes

Values of most pragmas are strings. Exceptions are:

- input:grab-depth,
- input:grab-limit,
- output:maxrows,
- sql:log-enable,
- sql:signal-void-variables

that have integer values.

Values of some pragmas a passed through the compiler to the run-time so they are seen in the generated SQL code as arguments of procedures:

- get:method,
- get:proxy,

- get:query,
- get:refresh,
- get:soft,
- get:uri

so sometimes you may meet them in SQL debuggers output and the like.

16.2.13. Built-in bif functions

- *bif:__rdf_long_from_batch_params(i_nt integer, st_value, st2_value)*

  - For value URI, the params values should be: 1, value.stringValue(), NULL
  - For value BNODE, the params values should be: 1, "_:"+((BNode)value).getID(), NULL
  - For value Literal with Language!=NULL, the params values should be: 5, lit.stringValue(), lit.getLanguage()
  - For value Literal with Datatype!=NULL, the params values should be: 4, lit.stringValue(), lit.getDatatype().toString()
  - For value Literal with Datatype==NULL && Language==NULL, the params values should be: 3, lit.stringValue(), NULL
  - For value any value exclude above, the params values should be: 3, value.stringValue(), NULL
  - For string value (without Datatype and Language), the params values should be: 3, value.stringValue(), NULL

Example:

```
SPARQL SELECT *
WHERE
  { graph ?g { `iri(??)` `iri(??)`
    `bif:__rdf_long_from_batch_params(3,value.stringValue(),NULL)` }
  }
```

16.2.14. Sending SOAP Requests to Virtuoso SPARQL Endpoint

This section presents a sample scenario on how to execute a SPARQL query as a SOAP request to the Virtuoso SPARQL Endpoint.

1. Assume the following sample SOAP request containing simple SPARQL query:

```
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/" xmlns:xsd="http://www.
   <soapenv:Body>
      <query-request xmlns="http://www.w3.org/2005/09/sparql-protocol-types/#">
         <query xmlns="">SELECT DISTINCT ?z FROM virtrdf: {?x ?y ?z .} LIMIT 10</query>
      </query-request>
   </soapenv:Body>
</soapenv:Envelope>
```

2. Save locally the content from above for ex. to file with the name "soap.xml".
3. To pass the SOAP request to a Virtuoso SPARQL Endpoint, execute the following curl command:

```
$ curl -d@soap.xml -H "Content-Type:text/xml" -H "SOAPAction: ''" http://example.com/sparql
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/">
  <soapenv:Body>
    <query-result xmlns="http://www.w3.org/2005/09/sparql-protocol-types/#">
      <sparql xmlns="http://www.w3.org/2005/sparql-results#" xmlns:xsi="http://www.w3.org/2001/XML
        <head>
         <variable name="z"/>
        </head>
        <results distinct="false" ordered="true">
          <result>
            <binding name="z">
             <uri>http://www.openlinksw.com/schemas/virtrdf#QuadMapFormat</uri>
            </binding>
          </result>
          <result>
            <binding name="z">
             <uri>http://www.openlinksw.com/schemas/virtrdf#QuadStorage</uri>
            </binding>
          </result>
          <result>
            <binding name="z">
```

```
          <uri>http://www.openlinksw.com/schemas/virtrdf#array-of-QuadMapFormat</uri>
        </binding>
      </result>
      <result>
        <binding name="z">
         <uri>http://www.openlinksw.com/schemas/virtrdf#QuadMap</uri>
        </binding>
      </result>
      <result>
        <binding name="z">
         <uri>http://www.openlinksw.com/schemas/virtrdf#QuadMapValue</uri>
        </binding>
      </result>
      <result>
        <binding name="z">
         <uri>http://www.openlinksw.com/schemas/virtrdf#array-of-QuadMapColumn</uri>
        </binding>
      </result>
      <result>
        <binding name="z">
         <uri>http://www.openlinksw.com/schemas/virtrdf#QuadMapColumn</uri>
        </binding>
      </result>
      <result>
        <binding name="z">
         <uri>http://www.openlinksw.com/schemas/virtrdf#array-of-QuadMapATable</uri>
        </binding>
      </result>
      <result>
        <binding name="z">
         <uri>http://www.openlinksw.com/schemas/virtrdf#QuadMapATable</uri>
        </binding>
      </result>
      <result>
        <binding name="z">
         <uri>http://www.openlinksw.com/schemas/virtrdf#QuadMapFText</uri>
        </binding>
      </result>
    </results>
  </sparql>
 </query-result>
</soapenv:Body>
</soapenv:Envelope>
```

16.2.15. Use of Hash Join With RDF

For queries that touch large quantities of RDF data and have many selection conditions, use of HASH JOIN is often desirable. For short lookup queries, HASH JOIN is usually not desirable.

Depending on the version, the query optimizer may or may not do HASH JOINs with RDF. This is controlled by the *hash_join_enable* flag.

To check the flag, do:

```
sys_stat ('hash_join_enable');
```

- 0 - means that hash joins are never made
- 1 - means that these are for SQL only
- 2 - means that these can also be used with RDF

The flag is set in the ini file in the [Flags] section:

```
[Flags]
hash_join_enable = 2
```

The flag may be transiently set with the SQL statement:

```
__dbf_set ('hash_join_enable', 2);
```

To check the effectiveness of HASH JOINs and whether the optimizer introduces these in the first place, it is most convenient to use the *profile* function.

In the following example, we look at the star schema benchmark Q4:

```
SPARQL PREFIX rdfh: <http://lod2.eu/schemas/rdfh#>
SELECT SUM(?rdfh_lo_revenue) AS ?lo_revenue ?d_year ?p_brand1
FROM <http://lod2.eu/schemas/rdfh-inst#ssb1_ttl_qb>
WHERE
  {
    ?li a rdfh:lineorder ;
        rdfh:lo_orderdate ?lo_orderdate ;
        rdfh:lo_partkey ?lo_partkey ;
        rdfh:lo_suppkey ?lo_suppkey ;
              rdfh:lo_revenue ?rdfh_lo_revenue .

    ?lo_orderdate rdfh:d_year ?d_year .
    ?lo_partkey rdfh:p_brand1 ?p_brand1 .
    ?lo_partkey rdfh:p_category "MFGR#12" .
    ?lo_suppkey rdfh:s_region "AMERICA" .
  }
GROUP BY ?d_year ?p_brand1
ORDER BY ?d_year ?p_brand1
;
```

The query aggregates rows from a large fact table and selects based on a date range, a brand, and the location of the supplier. To run this, it is best to put the query in a file and have profile ('sparql... ') wrapped around the text. Then, in isql:

```
SET SET BLOBS ON;
LOAD q4.sql;
```

Without HASH JOIN, the profile is:

```
{
time   1.9e-06% fanout         1 input         1 rows

```

These are runs on warm cache on a dataset of scale factor 30, about 3 billion triples.

We notice that the HASH-based plan completes faster and has a lower CPU percentage. This is to be expected since HASH JOINs are especially useful for JOINs between a large table and a smaller one.

The INDEX-based plan does 21M random INDEX lookups whereas the HASH-based one does only 11M. We also note that the INDEX access pattern is more local with the HASH plan, with 99% of lookups hitting the same segment as the previous, against only 85%.

These numbers are in the summary at the bottom of each profile:

- rnd -- means index access
- seq -- means rows retrieved in sequential scan; same seg is the percentage of index accesses that hit the same segment as the previous access.

The INDEX-based plan starts with the smallest selection; in this case, the days parts with the given brand. From this, it joins to the lineorder and gets the supplier. It fetches the region of the supplier and leaves out the ones not in America.

The HASH-based plan makes a hash table of all the parts with the brand, all the suppliers in America, and all the days in the time dimension. It then scans lineorder, and first drops the rows whose part is not in the hash, then drops the rows where the supplier is not in the hash, and then gets the year of each date. This last operation does not drop any rows, but is still done by hash, because there are relatively few days and the day-to-year translation is done a very large number of times.

The number of rows in and out of each operator is given after the time percent, above the operator. Fanout is the number of rows of output per one row of input.

Given the long-running queries of any workload, you can perform this same comparison to determine if HASH JOIN is useful in the case at hand. Looking at the real time and CPU% is usually enough.

- Using the sql:select-option pragma: One can specify the HASH JOIN is not to be used.

  ```
  define sql:select-option "loop"
  ```

  will exclude use of HASH JOIN in the specific query.
- The table_option construct can be used to select the JOIN type for any triple pattern.

  ```
  {
    ?lo rdfh:lo_suppkey ?supp .
    ?supp rdfh:s_region  "AMERICA" option (table_option "hash")
  }
  ```

  would have the effect of building a hash from the suppliers in America.

You may wish to experiment with these options and look at the profile output for each.

For some analytics workloads, enabling HASH JOIN may give a factor of 2 or 3 better performance. For lookup workloads, there may be no gain.

Sometimes a HASH JOIN may be used when an INDEX lookup would be better, thus in some cases it makes sense to turn off HASH JOINs either per query or globally.

16.3. Extensions

16.3.1. Using Full Text Search in SPARQL

Virtuoso's triple store supports optional full text indexing of RDF object values since version 5.0. It is possible to declare that objects of triples with a given predicate or graph get indexed. The graphs and triples may be enumerated or a wildcard may be used.

The triples for which a full text index entry exists can be found using the *bif:contains* or related filters and predicates.

For example, the query:

```
SQL>SELECT *
FROM <people>
WHERE
  {
    ?s foaf:Name ?name . ?name bif:contains "'rich*'".
  }
```

would match all subjects whose *foaf:Name* contain a word Rich. This would match Richard, Richie etc.

Note that words and phrases should be enclosed in quotes if they contain spaces or other non-alphanumeric chars.

If the *bif:contains* or related predicate is applied to an object that is not a string or is not the object of an indexed triple, no match will be found.

The syntax for text patterns is identical to the syntax for the SQL contains predicate.

The SPARQL/SQL optimizer determines whether the text pattern will be used to drive the query or whether it will filter results after other conditions are applied first. In contrast to *bif:contains* , regexp matching never drives the query or makes use of an index, thus in practice regexps are checked after other conditions.

Specifying What to Index

Whether the object of a given triple is indexed in the text index depends on indexing rules. If at least one indexing rule matches the triple, the object gets indexed if the object is a string. An indexing rule specifies a graph and a predicate. Either may be an IRI or NULL, in which case it matches all IRI's.

Rules also have a 'reason', which can be used to group rules into application-specific sets. A triple will stop being indexed only after all rules mandating its indexing are removed. When an application requires indexing a certain set of triples, rules are added for that purpose. These rules are tagged with the name of the application as their reason. When an application no longer requires indexing, the rules belonging to this application can be removed. This will not turn off indexing if another application still needs certain triples to stay indexed.

Indexing is enabled/disabled for specific graph/predicate combinations with:

```
create function DB.DBA.RDF_OBJ_FT_RULE_ADD
  (in rule_g varchar, in rule_p varchar, in reason varchar) returns integer

create function DB.DBA.RDF_OBJ_FT_RULE_DEL
  (in rule_g varchar, in rule_p varchar, in reason varchar) returns integer
```

Example: The first function adds a rule. The first two arguments are the text representation of the IRI's for the graph and predicate. If NULL is given then all graph's or predicates match. Specifying both as NULL means that all string valued objects will be added to a text index.

Example:

```
DB.DBA.RDF_OBJ_FT_RULE_ADD (null, null, 'All');
```

The second function reverses the effect of the first. Only a rule that has actually been added can be deleted. Thus one cannot say that all except a certain enumerated set should be indexed.

```
DB.DBA.RDF_OBJ_FT_RULE_DEL (null, null, 'All');
```

The reason argument is an arbitrary string identifying the application that needs this rule. Two applications can add the same rule. Removing one of them will still keep the rule in effect. If an object is indexed by more than one rule, the index data remain free from duplicates, neither index size nor speed is affected.

If *DB.DBA.RDF_OBJ_FT_RULE_ADD* detects that *DB.DBA.RDF_QUAD* contains quads whose graphs and/or predicates match to the new rule but which have not been indexed before then these quads are indexed automatically. However the function *DB.DBA.RDF_OBJ_FT_RULE_DEL* does not remove indexing data about related objects. Thus the presence of indexing data about an object does not imply that it is necessarily used in some quad that matches to some rule.

The above functions return one if the rule is added or deleted and zero if the call was redundant (the rule has been added before or there's no rule to delete).

Example

```
-- We load Tim Berners-Lee's FOAF file into a graph called 'people'.

SQL>DB.DBA.RDF_LOAD_RDFXML (http_get ('http://www.w3.org/People/Berners-Lee/card#i'), 'no', 'http://www.w
Done. -- 172 msec.

-- We check how many triples we got.

SQL>SPARQL SELECT COUNT (*) FROM <http://www.w3.org/people#> WHERE {?s ?p ?o};
callret-0
INTEGER
 266
No. of rows in result: 1

-- We check the GRAPH: <http://www.w3.org/people#> for objects like "Tim":

SQL>SPARQL
SELECT *
FROM <http://www.w3.org/people#>
WHERE
  {
    ?s ?p ?o . FILTER (?o LIKE '%Tim%')
  };
s                                                 p                                                 o
VARCHAR                                           VARCHAR                                           VARCHAR

-- of all triples in the GRAPH: <http://www.w3.org/people#>,
-- where the object is a string which contains a word beginning with "TIM".
```

```
SQL>SPARQL SELECT * FROM <http://www.w3.org/people#> WHERE { ?s ?p ?o . ?o bif:contains '"Timo*"'};
s                                                 p                                   o
VARCHAR                                           VARCHAR                             VARCHAR
_______________________________________________________________________________

 http://www.w3.org/People/Berners-Lee/card#i    http://xmlns.com/foaf/0.1/name        Timothy Berners-Lee
 http://www.w3.org/People/Berners-Lee/card#i    http://xmlns.com/foaf/0.1/givenname   Timothy

2 Rows. -- 2 msec.
```

The query below is identical with that above but uses a different syntax. The filter syntax is more flexible in that it allows passing extra options to the *contains* predicate. These may be useful in the future.

```
SQL>SPARQL SELECT * FROM <people> WHERE { ?s ?p ?o . FILTER (bif:contains(?o,  '"Timo*"')) };
```

Note:

It is advisable to upgrade to the latest version of Virtuoso before adding free-text rules for the first time. This is especially the case if large amounts of text are to be indexed. The reason is that the free-text index on RDF may be changed in future versions and automatic upgrading of an existing index data into the new format may take much more time than indexing from scratch.

The table *DB.DBA.RDF_OBJ_FT_RULES* stores list of free-text index configuration rules.

```
create table DB.DBA.RDF_OBJ_FT_RULES (
  ROFR_G varchar not null,       -- specific graph IRI or NULL for "all graphs"
  ROFR_P varchar not null,       -- specific predicate IRI or NULL for "all predicates"
  ROFR_REASON varchar not null,  -- identification string of a creator, preferably human-readable
  primary key (ROFR_G, ROFR_P, ROFR_REASON) );
```

Applications may read from this table but they should not write to it directly. Duplications in the rules do not affect the speed of free-text index operations because the content of the table is cached in memory in a special form. Unlike the use of configuration functions, directly writing to the table will not update the in-memory cache.

The table is convenient to search for rules added by a given application. If a unique identification string is used during installation of an application when rules are added then it's easy to remove those rules as part of any uninstall routine.

Time of Indexing

The triple store's text index is in manual batch mode by default. This means that changes in triples are periodically reflected in the text index but are not maintained in strict synchrony. This is much more efficient than keeping the indices in constant synchrony. This setting may be altered with the *db.dba.vt_batch_update* stored procedure.

To force synchronization of the RDF text index, use:

```
DB.DBA.VT_INC_INDEX_DB_DBA_RDF_OBJ ();
```

To set the text index to follow the triples in real time, use:

```
DB.DBA.VT_BATCH_UPDATE ('DB.DBA.RDF_OBJ', 'OFF', null);
```

To set the text index to be updated every 10 minutes, use:

```
DB.DBA.VT_BATCH_UPDATE ('DB.DBA.RDF_OBJ', 'ON', 10);
```

To make the update always manual, specify NULL as the last argument above.

One problem related to free-text indexing of *DB.DBA.RDF_QUAD* is that some applications (e.g. those that import billions of triples) may set off triggers. This will make free-text index data incomplete. Calling procedure *DB.DBA.RDF_OBJ_FT_RECOVER ()* will insert all missing free-text index items by dropping and re-inserting every existing free-text index rule.

Free-Text Indexes on Linked Data Views

If an *O* field of a quad map pattern gets its value from a database column that has a free text index then this index can be used in SPARQL for efficient text searching. As a variation of this facility, the free-text index of another table may be used.

If a statement of a quad map pattern declaration starts with a declaration of table aliases, the table alias declaration may include the name of a table column that should have a text index. For example, consider the possibility of using a free-text index on the content of DAV resources stored in the DAV system tables of Virtuoso:

```
prefix mydav: <...>
create quad storage mydav:metadata
FROM WS.WS.SYS_DAV_RES as dav_resource text literal RES_CONTENT
...
  {
    ...
    mydav:resource-iri (dav_resource.RES_FULL_PATH)
        a mydav:resource ;
        mydav:resource-content dav_resource.RES_CONTENT ;
        mydav:resource-mime-type dav_resource.RESTYPE ;
    ...
  }
```

The clause *text literal RES_CONTENT* grants the SPARQL compiler permission to use a free-text index for objects that are literals composed from column *dav_resource.RES_CONTENT* . This clause also allows choosing between *text literal* (supports only the *contains()* predicate) and *text xml literal* (supports both *contains()* and *xcontains()*) text indexes. It is important to understand that the free-text index will produce results using raw relational data. If a literal class transformation changes the text stored in the column then these changes are ignored by free-text search. e.g. if a transformation concatenates a word to the value of the column, but the free-text search will not find this word.

The free-text index may be used in a more sophisticated way. Consider a built-in table *DB.DBA.RDF_QUAD* that does not have a free-text index. Moreover, the table does not contain the full values of all objects; the *O* column contains "short enough" values inlined, but long and special values are represented by links to the *DB.DBA.RDF_OBJ* table. The RDF_OBJ table, however, has free-text index that can be used. The full declaration of the built-in default mapping for default storage could be written this way:

```
-- Important! Do not try to execute on live system
-- without first changing the quad storage and quad map pattern names!

SPARQL
create virtrdf:DefaultQuadMap as
graph rdfdf:default-iid-nonblank (DB.DBA.RDF_QUAD.G)
subject rdfdf:default-iid (DB.DBA.RDF_QUAD.S)
predicate rdfdf:default-iid-nonblank (DB.DBA.RDF_QUAD.P)
object rdfdf:default (DB.DBA.RDF_QUAD.O)

create quad storage virtrdf:DefaultQuadStorage
FROM DB.DBA.RDF_QUAD as physical_quad
FROM DB.DBA.RDF_OBJ as physical_obj text xml literal RO_DIGEST of (physical_quad.O)
WHERE (^{physical_quad.}^.O = ^{physical_obj.}^.RO_DIGEST)
  {
    create virtrdf:DefaultQuadMap as
      graph rdfdf:default-iid-nonblank (physical_quad.G)
      subject rdfdf:default-iid (physical_quad.S)
      predicate rdfdf:default-iid-nonblank (physical_quad.P)
      object rdfdf:default (physical_quad.O) .
  }
;
```

The reference to the free-text index is extended by clause *of (physical_quad.O)* . This means that the free-text on *DB.DBA.RDF_OBJ.RO_DIGEST* will be used when the object value comes from *physical_quad.O* as if *physical_quad.O* were indexed itself. If a SPARQL query invokes *virtrdf:DefaultQuadMap* but contains no free-text criteria then only *DB.DBA.RDF_QUAD* appears in the final SQL statement and no join with *DB.DBA.RDF_OBJ* is made. Adding a free-text predicate will add *DB.DBA.RDF_OBJ* to the list of source tables and a join condition for *DB.DBA.RDF_QUAD.O* and *DB.DBA.RDF_OBJ.RO_DIGEST* ; and it will add *contains (RO_DIGEST, ...)* predicate, rather than *contains (O, ...)* . As a result, "you pay only for what you use": adding free-text index to the declaration does not add tables to the query unless the index is actually used.

Boolean functions `bif:contains` and `bif:xcontains` are used for objects that come from Linked Data Views as well as for regular "physical" triples. Every function takes two arguments and returns a boolean value. The first argument is an local variable. The argument variable should be used as an object field in the group pattern where the filter condition is placed. Moreover, the occurrence of the variable in an object field should be placed *before* the filter. If there are many occurrences of the variable in object fields then the free-text search is associated with the rightmost occurrence that is still to the left of the filter. The triple pattern that contains the rightmost occurrence is called the "intake" of the free-text search. When the SPARQL compiler chooses the appropriate quad map patterns that may generate data matching the intake triple pattern, it skips quad map patterns that have no declared free-text indexes, because nothing can be found by free-text search in data that have no free-text index. Every quad map pattern that has a free-text pattern will ultimately produce an invocation of the SQL contains or xcontains predicate, so the final result of a free-text search may be a union of free-text searches from different quad map patterns.

The described logic is important only in very complicated cases, whereas simple queries are self-evident:

```
SELECT * FROM <my-dav-graph>
WHERE {
    ?resource a mydav:resource ;
        mydav:resource-content ?text .
    FILTER (bif:contains (?text, "hello and world")) }
```

or, more succinctly,

```
SELECT * FROM <my-dav-graph>
WHERE {
    ?resource a mydav:resource ;
        mydav:resource-content ?text .
    ?text bif:contains "hello and world" . }
```

Example Using Score

```
SQL>
SPARQL
SELECT *
WHERE
  {
    ?s ?p ?o .
    ?o bif:contains 'NEW AND YORK'
    OPTION (score ?sc) .
  }
ORDER BY DESC (?sc)
LIMIT 10

s                                                                    p
ANY                                                                  ANY

16.3.2. SPARUL -- an Update Language For RDF Graphs

Introduction

Starting with version 5.0, Virtuoso supports the SPARQL/Update extension to SPARQL. This is sufficient for most of routine data manipulation operations. If the *SPARQL_UPDATE* role is granted to user *SPARQL* user then data manipulation statements may be executed via the SPARQL web service endpoint as well as by data querying.

Manage RDF Storage

Two functions allow the user to alter RDF storage by inserting or deleting all triples listed in some vector. Both functions receive the IRI of the graph that should be altered and a vector of triples that should be added or removed. The graph IRI can be either an IRI ID or a string. The third optional argument controls the transactional behavior - the parameter value is passed to the `log_enable` function. The return values of these functions are not defined and should not be used by applications.

```
create function DB.DBA.RDF_INSERT_TRIPLES (in graph_iri any, in triples any, in log_mode integer := null)
create function DB.DBA.RDF_DELETE_TRIPLES (in graph_iri any, in triples any, in log_mode integer := null)
```

Simple operations may be faster if written as low-level SQL code instead of using SPARUL. The use of SPARQL DELETE is unnecessary in cases where the better alternative is for the application to delete from RDF_QUAD using simple SQL filters like:

```
DELETE FROM DB.DBA.RDF_QUAD
WHERE G = DB.DBA.RDF_MAKE_IID_OF_QNAME (
    'http://local.virt/DAV/sparql_demo/data/data-xml/source-simple2/source-data-01.rdf' );
```

On the other hand, simple filters does not work when the search criteria refer to triples that are affected by the modification. Consider a function that deletes all triples whose subjects are nodes of type 'http://xmlns.com/foaf/0.1/Person'. Type information is stored in triples that will be deleted, so the simplest function is something like this:

```
create procedure DELETE_PERSONAL_DATA (in foaf_graph varchar)
{
  declare pdata_dict, pdata_array any;
-- Step 1: select everything that should be deleted
  pdata_dict := ((
      sparql construct { ?s ?p ?o }
      WHERE { graph ?:foaf_graph {
              ?s ?p ?o . ?s rdf:type <http://xmlns.com/foaf/0.1/Person>
            } }
      ));
-- Step 2: delete all found triples
  pdata_array := dict_list_keys (pdata_dict, 1);
  RDF_DELETE_TRIPLES (foaf_graph, pdata_array);
};

DELETE_PERSONAL_DATA (
  'http://local.virt/DAV/sparql_demo/data/data-xml/source-simple2/source-data-01.rdf' );
```

From Virtuoso 5.0 onwards, applications can use SPARUL to do the same in a more convenient way:

```
create procedure DELETE_PERSONAL_DATA (in foaf_graph varchar)
{
  sparql delete { ?s ?p ?o }
      WHERE { graph ?:foaf_graph {
              ?s ?p ?o . ?s rdf:type <http://xmlns.com/foaf/0.1/Person>
            } }
};
```

Examples

Example for changing the graph

The graph to be changed may be specified by an option preceding of query, instead of being specified in the 'insert into graph' clause.

```
SQL>SPARQL DEFINE input:default-graph-uri <http://mygraph.com>
INSERT INTO <http://mygraph.com> { <http://example.com/dataspace/Kingsley#this> <http://www.w3.org/1999/0
callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://mygraph.com>, 1 triples -- done

1 Rows. -- 20 msec.
```

Example for delete graph equivalence

The following two statements are equivalent but the latter may work faster, especially if there are many Linked Data Views in the system or if the graph in question contains triples from Linked Data Views. Note that neither of these two statements affects data coming from Linked Data Views.

```
SQL> SPARQL DELETE FROM GRAPH <http://mygraph.com> { ?s ?p ?o } FROM <http://mygraph> WHERE { ?s ?p ?o };
callret-0
VARCHAR
_______________________________________________________________________________

Delete from <http://mygraph.com>, 1 triples -- done

1 Rows. -- 10 msec.

SQL> SPARQL CLEAR GRAPH <http://mygraph.com>;
callret-0
VARCHAR
_______________________________________________________________

Clear <http://mygraph.com> -- done

1 Rows. -- 10 msec.
```

DROP GRAPH is equivalent of CLEAR GRAPH. It requires initially the graph to be created explicitly.

Note: All SPARQL commands should work via SPARUL (i.e. executed from the /sparql endpoint) as soon as "SPARQL" user has "SPARQL_UPDATE" privilege.

Assume the following sequence of commands to be executed from the /sparql endpoint:

- Create explicitly a graph:

  ```
  CREATE GRAPH <qq>

  callret-0
  Create graph <qq> -- done
  ```
- If you don't know whether the graph is created explicitly or not, use

  DROP SILENT GRAPH

  :

  ```
  DROP SILENT     GRAPH <qq>

  callret-0
  Drop silent graph <qq> -- done
  ```
- If you know the graph is created explicitly, use

  DROP GRAPH

  :

  ```
  DROP GRAPH <qq>

  callret-0
  Drop graph <qq> -- done
  ```

Example for deleting all triples for given subject

The following statement deletes all records with <http://example.com/dataspace/Kingsley#this> as the subject:

```
SQL>SPARQL
DELETE FROM GRAPH <http://mygraph.com> { ?s ?p ?o }
FROM <http://mygraph.com>
WHERE { ?s ?p ?o . filter ( ?s = <http://example.com/dataspace/Kingsley#this>) };
callret-0
```

```
VARCHAR
_______________________________________________________________________________

Delete from <http://mygraph.com>, 1 triples -- done

1 Rows. -- 10 msec.
```

Alternatively, the statement can be written in this way:

```
SQL>SPARQL
DELETE FROM GRAPH <http://mygraph.com> { <http://example.com/dataspace/Kingsley#this> ?p ?o }
FROM <http://mygraph.com>
WHERE { <http://example.com/dataspace/Kingsley#this> ?p ?o };
callret-0
VARCHAR
_______________________________________________________________________________

Delete from <http://mygraph.com>, 1 triples -- done

1 Rows. -- 10 msec.
```

Example for INSERT statements equivalent

Keywords 'insert in' and 'insert into' are interchangeable in Virtuoso for backward compatibility, but the SPARUL specification lists only 'insert into'. For example, the statements below are equivalent:

```
SQL>SPARQL INSERT INTO GRAPH <http://mygraph.com> {  <http://example.com/dataspace/Kingsley#this>
                                                     <http://rdfs.org/sioc/ns#id>
                                                     <Kingsley> };
callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://mygraph.com>, 1 triples -- done

1 Rows. -- 0 msec.
SQL>SPARQL INSERT INTO GRAPH <http://mygraph.com> {  <http://example.com/dataspace/Caroline#this>
                                                     <http://www.w3.org/1999/02/22-rdf-syntax-ns#type>
                                                     <http://rdfs.org/sioc/ns#User> };
callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://mygraph.com>, 1 triples -- done

1 Rows. -- 0 msec.

-- and

SQL>SPARQL INSERT IN GRAPH <http://mygraph.com> {  <http://example.com/dataspace/Kingsley#this>
                                                   <http://rdfs.org/sioc/ns#id>
                                                   <Kingsley> };
callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://mygraph.com>, 1 triples -- done

1 Rows. -- 10 msec.
SQL>SPARQL INSERT IN GRAPH <http://mygraph.com> {  <http://example.com/dataspace/Caroline#this>
                                                   <http://www.w3.org/1999/02/22-rdf-syntax-ns#type>
                                                   <http://rdfs.org/sioc/ns#User> };
callret-0
VARCHAR
_______________________________________________________________________

Insert into <http://mygraph.com>, 1 triples -- done

1 Rows. -- 0 msec.
```

Example for various expressions usage

It is possible to use various expressions to calculate fields of new triples. This is very convenient, even if not a part of the original specification.

```
SQL>SPARQL INSERT INTO GRAPH <http://mygraph.com> { ?s <http://rdfs.org/sioc/ns#id> `iri (bif:concat (str
WHERE { ?s <http://rdfs.org/sioc/ns#id> ?o };
callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://mygraph.com>, 4 triples -- done

1 Rows. -- 0 msec.
```

Example for operator IN usage

The example shows how to find which predicate/object pairs the following subjects have in common and count the occurances:

```
http://dbpedia.org/resource/Climate_change
http://dbpedia.org/resource/Disaster_risk_reduction
http://dbpedia.org/resource/Tanzania
http://dbpedia.org/resource/Capacity_building
http://dbpedia.org/resource/Poverty
http://dbpedia.org/resource/Construction
http://dbpedia.org/resource/Vulnerability
http://dbpedia.org/resource/Mount_Kilimanjaro
http://dbpedia.org/resource/Social_vulnerability
```

The following query returns the desired results:

```
SPARQL
SELECT ?s1 ?s2 COUNT (1)
WHERE
  {
    ?s1 ?p ?o .
    FILTER (?s1 IN (<http://dbpedia.org/resource/Climate_change>,
    <http://dbpedia.org/resource/Disaster_risk_reduction>,
    <http://dbpedia.org/resource/Tanzania>,
    <http://dbpedia.org/resource/Capacity_building>,
    <http://dbpedia.org/resource/Poverty>,
    <http://dbpedia.org/resource/Construction>,
    <http://dbpedia.org/resource/Vulnerability>,
    <http://dbpedia.org/resource/Mount_Kilimanjaro>,
    <http://dbpedia.org/resource/Social_vulnerability> ))
    ?s2 ?p ?o .
    FILTER (?s2 IN (<http://dbpedia.org/resource/Climate_change>,
    <http://dbpedia.org/resource/Disaster_risk_reduction>,
    <http://dbpedia.org/resource/Tanzania>,
    <http://dbpedia.org/resource/Capacity_building>,
    <http://dbpedia.org/resource/Poverty>,
    <http://dbpedia.org/resource/Construction>,
    <http://dbpedia.org/resource/Vulnerability>,
    <http://dbpedia.org/resource/Mount_Kilimanjaro>,
    <http://dbpedia.org/resource/Social_vulnerability> ))
    FILTER (?s1 != ?s2)
    FILTER (str(?s1) < str (?s2))
  }
LIMIT 20
```

The result of executing the query:

```
s1                                          s2                                                cal
http://dbpedia.org/resource/Climate_change       http://dbpedia.org/resource/Tanzania                 2
http://dbpedia.org/resource/Social_vulnerability http://dbpedia.org/resource/Vulnerability            1
http://dbpedia.org/resource/Mount_Kilimanjaro    http://dbpedia.org/resource/Poverty                  1
http://dbpedia.org/resource/Mount_Kilimanjaro    http://dbpedia.org/resource/Tanzania                 3
http://dbpedia.org/resource/Capacity_building    http://dbpedia.org/resource/Disaster_risk_reduction  1
http://dbpedia.org/resource/Poverty              http://dbpedia.org/resource/Tanzania                 1
```

You can also find live demo query results here

Example usage of IN operator for retrieving all triples for each entity.

Example for Modify used as Update

'Modify graph' may be used as a form of 'update' operation.

```
-- update a graph with insert scoped on the same graph
SQL>SPARQL
MODIFY GRAPH <http://mygraph.com>
DELETE { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type> ?o }
INSERT { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type1> ?o }
FROM <http://mygraph.com>
WHERE { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type> ?o };

-- update a graph with insert scoped on another graph
SQL>SPARQL
MODIFY GRAPH <http://mygraph.com>
DELETE { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type> ?o }
INSERT { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type1> ?o }
FROM <http://example.com>
WHERE { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type> ?o };

-- update a graph with insert scoped over the whole RDF Quad Store
SQL>SPARQL
MODIFY GRAPH <http://mygraph.com>
DELETE { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type> ?o }
INSERT { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type1> ?o }
WHERE { ?s <http://www.w3.org/1999/02/22-rdf-syntax-ns#type> ?o };

-- update a graph with delete of particular tripple
SQL>SPARQL
DELETE FROM GRAPH <http://mygraph.com> { <http://example.com/dataspace/Caroline#this> <http://www.w3.org/
```

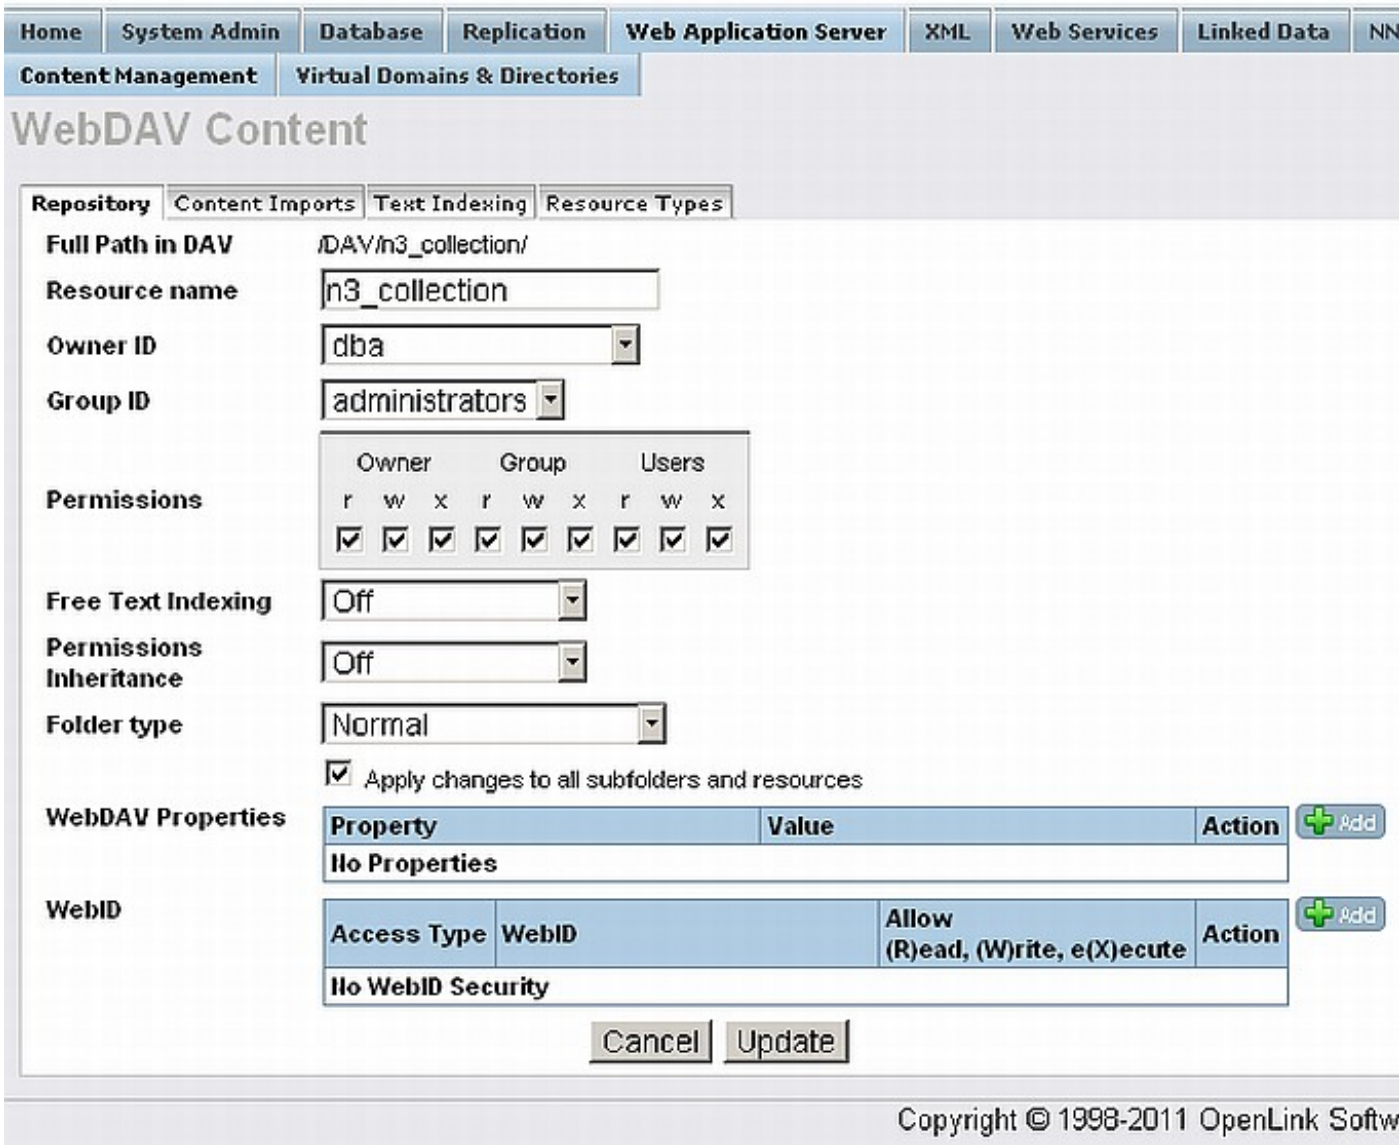
Example for generating RDF information resource URI

The RDF information resource URI can be generated via a string expression.

1. Suppose there is a sample file kidehen.n3:

```
<http://www.openlinksw.com/dataspace/person/kidehen@openlinksw.com#this> <http://www.w3.org/1999/0
<http://www.openlinksw.com/dataspace/person/kidehen@openlinksw.com#this> <http://www.w3.org/2000/0
<http://www.openlinksw.com/dataspace/person/kidehen@openlinksw.com#this> <http://rdfs.org/sioc/ns#
```

2. Using Conductor UI go to Web Application Server and create folder, for ex. with name "n3_collection"
3. Upload the "n3_collection" folder the file kidehen.n3
4. Click properties for the folder "n3_collection" and set to be public readable in the Permissions section
5. Check "Apply changes to all subfolders and resources".
6. Finally Click "Update"
7. **Figure 16.44. Generating RDF information resource URI**



8. To clear the graph execute:

```
SQL>SPARQL CLEAR GRAPH <http://mygraph.com>;
callret-0
VARCHAR
_______________________________________________________________________

Clear <http://mygraph.com> -- done

1 Rows. -- 10 msec.
```

9. To load the kidehen.n3 file execute:

```
SQL>SPARQL
load bif:concat ("http://", bif:registry_get("URIQADefaultHost"), "/DAV/n3_collection/kidehen.n3")
INTO GRAPH <http://mygraph.com>;
callret-0
VARCHAR
_______________________________________________________________________________

Load <http://example.com/DAV/n3_collection/kidehen.n3> into graph <http://mygraph.com> -- done

1 Rows. -- 30 msec.
```

10. In order to check the new inserted triples execute:

```
SQL>SPARQL
SELECT *
FROM <http://mygraph.com>
WHERE
```

```
  {
    ?s ?p ?o
  }
;
s                                                                    p
VARCHAR                                                              VARCHAR

Examples for Modify used as Update

Example for Dropping graph

When handling very large RDF data collections (e.g. 600 million triples) loaded into Virtuoso server as a single graph, the fastest operation to drop the graph is:

```
SQL>SPARQL CLEAR GRAPH <http://mygraph.com>;
callret-0
VARCHAR
_____________________________________________________________________________

Clear <http://mygraph.com> -- done

1 Rows. -- 10 msec.
```

The operation can be speeded up by executing log_enable (0) or even log_enable (2) beforehand, and log_enable(1) after it completes.

Example for testing Graph Equality

The procedure below keeps simple cases of graphs with bnodes:

1. First it compares all triples without bnodes
2. Then it iteratively establishes equivalences between bnodes that are directly and unambiguously connected to equivalent vertexes by identical predicates.

```
-- Fast Approximate RDF Graph Equivalence Test
-- (C) 2009-2020 OpenLink Software
-- License: GNU General Public License (only version 2 of the license).
-- No warranty, even implied warranty

-- This compares the content of triple dictionaries \c dict1 and \c dict2,
-- returns NULL if no difference found (with bnode equivalence in mind),
-- returns description of a difference otherwise.
-- The function is experimental (note suffix _EXP), so no accurate QA is made.
-- Some version of the function may be inserted later in OpenLink Virtuoso Server under some different na
create function DB.DBA.RDF_TRIPLE_DICTS_DIFFER_EXP (
  in dict1 any, --- Triple dictionary, traditional, (vectors of S, P, O are keys, any non-nulls are value
  in dict2 any, --- Second triple dictionary, like to \c dict1

Examples for Modify used as Update

Example for Deleting triples from graph

The example below has a request to delete all records of old books (dated before year 2000)

```
SQL>SPARQL
PREFIX dc:  <http://purl.org/dc/elements/1.1/>
PREFIX xsd: <http://www.w3.org/2001/XMLSchema#>
DELETE FROM GRAPH <http://BookStore.com> { ?book ?p ?v }
WHERE
  { GRAPH  <http://BookStore.com>
   { ?book dc:date ?date
     FILTER ( xsd:dateTime(?date) < xsd:dateTime("2000-01-01T00:00:00")).
    ?book ?p ?v.
   }
  };
_______________________________________________________________________________

Delete from <http://BookStore.com>, 6 triples -- done
```

```
1 Rows. -- 10 msec.
```

Example for Copying triples from one graph to another

The next snippet copies records from one named graph to another based on a pattern:

```
SQL>SPARQL clear graph <http://BookStore.com>;
SQL>SPARQL clear graph <http://NewBookStore.com>;
SQL>SPARQL
insert in graph <http://BookStore.com>
  {
    <http://www.dajobe.org/foaf.rdf#i> <http://purl.org/dc/elements/1.1/date> <1999-04-01T00:00:00> .
    <http://www.w3.org/People/Berners-Lee/card#i> <http://purl.org/dc/elements/1.1/date> <1998-05-03T00:0
    <http://www.w3.org/People/Connolly/#me> <http://purl.org/dc/elements/1.1/date> <2001-02-08T00:00:00>
  };
SQL>SPARQL
PREFIX dc:  <http://purl.org/dc/elements/1.1/>
PREFIX xsd: <http://www.w3.org/2001/XMLSchema#>
INSERT INTO GRAPH <http://NewBookStore.com> { ?book ?p ?v }
WHERE
  { GRAPH  <http://BookStore.com>
   { ?book dc:date ?date
     FILTER ( xsd:dateTime(?date) > xsd:dateTime("2000-01-01T00:00:00")).
     ?book ?p ?v.
   }
  };
callret-0
VARCHAR
_____________________________________________________________________________

Insert into <http://NewBookStore.com>, 6 triples -- done

1 Rows. -- 30 msec.
```

Example for Moving triples from one graph to another

This example moves records from one named graph to another named graph based on a pattern:

```
SQL>SPARQL
PREFIX dc:  <http://purl.org/dc/elements/1.1/>
PREFIX xsd: <http://www.w3.org/2001/XMLSchema#>

INSERT INTO GRAPH <http://NewBookStore.com>
 { ?book ?p ?v }
WHERE
  { GRAPH  <http://BookStore.com>
     { ?book dc:date ?date .
       FILTER ( xsd:dateTime(?date) > xsd:dateTime("2000-01-01T00:00:00")).
       ?book ?p ?v.
     }
  };
_____________________________________________________________________________

Insert into <http://NewBookStore.com>, 6 triples -- done

1 Rows. -- 10 msec.

SQL>SPARQL
PREFIX dc:  <http://purl.org/dc/elements/1.1/>
PREFIX xsd: <http://www.w3.org/2001/XMLSchema#>
DELETE FROM GRAPH <http://BookStore.com>
 { ?book ?p ?v }
WHERE
  { GRAPH  <http://BookStore.com>
      { ?book dc:date ?date .
        FILTER ( xsd:dateTime(?date) > xsd:dateTime("2000-01-01T00:00:00")).
        ?book ?p ?v.
      }
  };
_____________________________________________________________________________
```

```
Delete from <http://BookStore.com>, 3 triples -- done

1 Rows. -- 10 msec.
```

Example for BBC SPARQL Collection

Example usage of IN operator for retrieving all triples for each entity

To retrieve all triples for each entity for a given list of entities uris, one might use the following syntax:

```
SELECT ?p ?o
WHERE
  {
    ?s ?p ?o .
    FILTER ( ?s IN (<someGraph#entity1>, <someGraph#entity2>, ...<someGraph#entityN> ) )
  }
```

So to demonstrate this feature, execute the following query:

```
SQL>SPARQL
SELECT DISTINCT ?p ?o
WHERE
  {
    ?s ?p ?o .
    FILTER ( ?s IN (<http://dbpedia.org/resource/Climate_change>, <http://dbpedia.org/resource/Social_vul
  }
LIMIT 100

p                                                       o
ANY                                                     ANY
_______________________________________________________________________________
```

Note that the query will not show anything when there are triples like:

```
<x> <y> "In"
<z> <q> "Your"
```

Example for extending SPARQL via SQL for Full Text search: Variant II

To get movies from DBpedia, where the query can contain terms from the title, one might use the following syntax:

```
SQL>SPARQL
 SELECT ?s ?an ?dn ?o( bif:search_excerpt ( bif:vector ( 'Broken', 'Flowers' ) , ?o ) )
 WHERE
  {
    ?s rdf:type dbpedia-owl:Film .
    ?s dbpprop:name ?o .
    FILTER ( bif:contains ( ?o, '"broken flowers"' ) )
    OPTIONAL { ?s dbpprop:starring ?starring .}
    OPTIONAL { ?s dbpprop:director ?director . }
    OPTIONAL { ?starring dbpprop:name ?an . }
    OPTIONAL { ?director dbpprop:name ?dn . }
  };

http://dbpedia.org/resource/Broken_Flowers  Tilda Swinton       Jim Jarmusch    Broken Flowers
http://dbpedia.org/resource/Broken_Flowers      Swinton, Tilda  Jim Jarmusch      Broken Flowers
....
http://dbpedia.org/resource/Broken_Flowers  Bill Murray           Jim Jarmusch          Music from Broken
....
```

Note that the query will not show anything when there are triples like:

```
<x> <y> "Broken"
<z> <q> "Flowers"
```

Example for date manipulation of xsd types within SPARQL

This example shows usage of dateTime column truncation to date only and performs a group by on this column:

```
-- prepare the data by inserting triples in a graph:

```

Example for executing INSERT/DELETE (SPARUL) statements against a WebID protected SPARQL endpoint

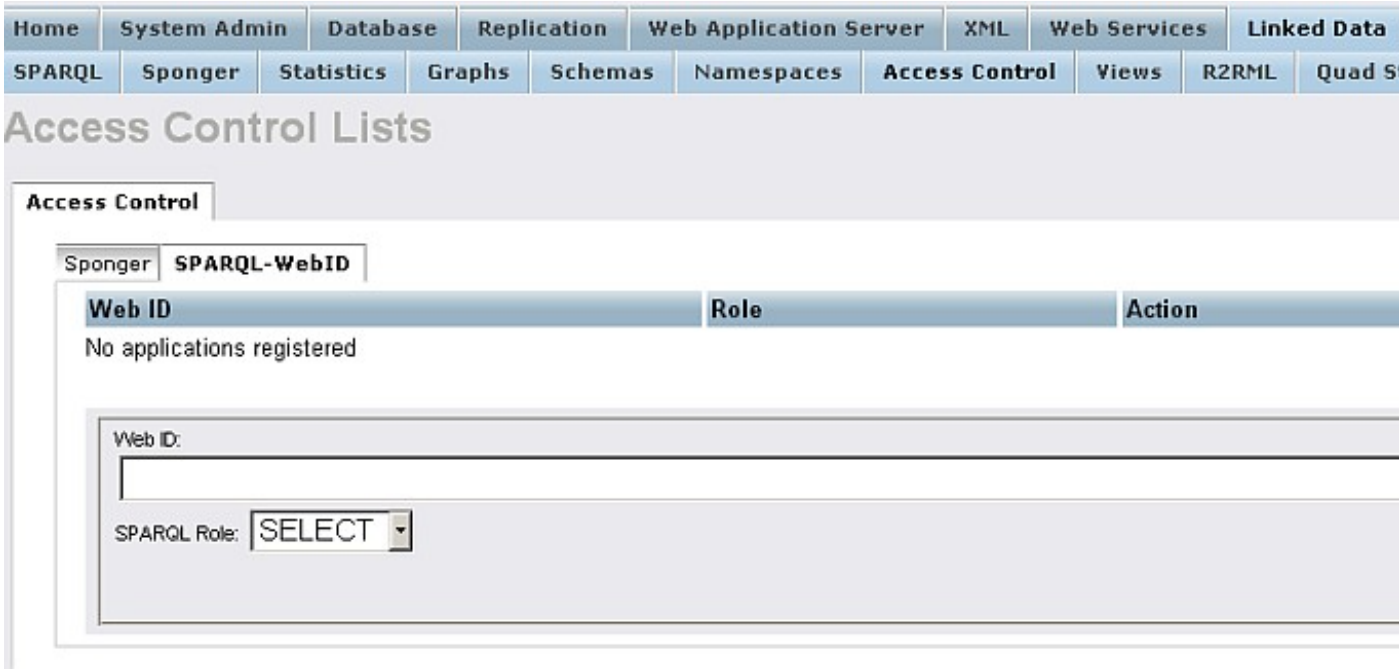
The following sample scenario demonstrates how to perform INSERT/DELETE (SPARUL) statements against a protected SPARQL Endpoint by setting WebID Protocol ACLs using the Virtuoso Authentication Server UI:

1. Obtain a WebID:
    a. Download and install the ods_framework_dav.vad .
        - Note: an existing ODS DataSpace user instance can also be used, for example at http://id.myopenlink.net/ods/
    b. Register an ODS Data Space user, for example with name "demo".
    c. The generated WebID will be for example:

        ```
        http://id.myopenlink.net/dataspace/person/demo#this
        ```

    d. Generate a Personal HTTP based Identifier for the "demo" user and then bind the personal Identifier to an X.509 Certificate, thereby giving assigning the user a WebID.
2. Download and install the conductor_dav.vad package, if not already installed.
3. Go to http://<cname>:<port>/conductor, where <cname>:<port> are replaced by your local server values.
4. Go to System Admin -> Linked Data -> Access Control -> SPARQL-WebID

Figure 16.45. Conductor SPARQL-WebID



5. In the displayed form:

   a. Enter the Web ID for the user registered above, for example:

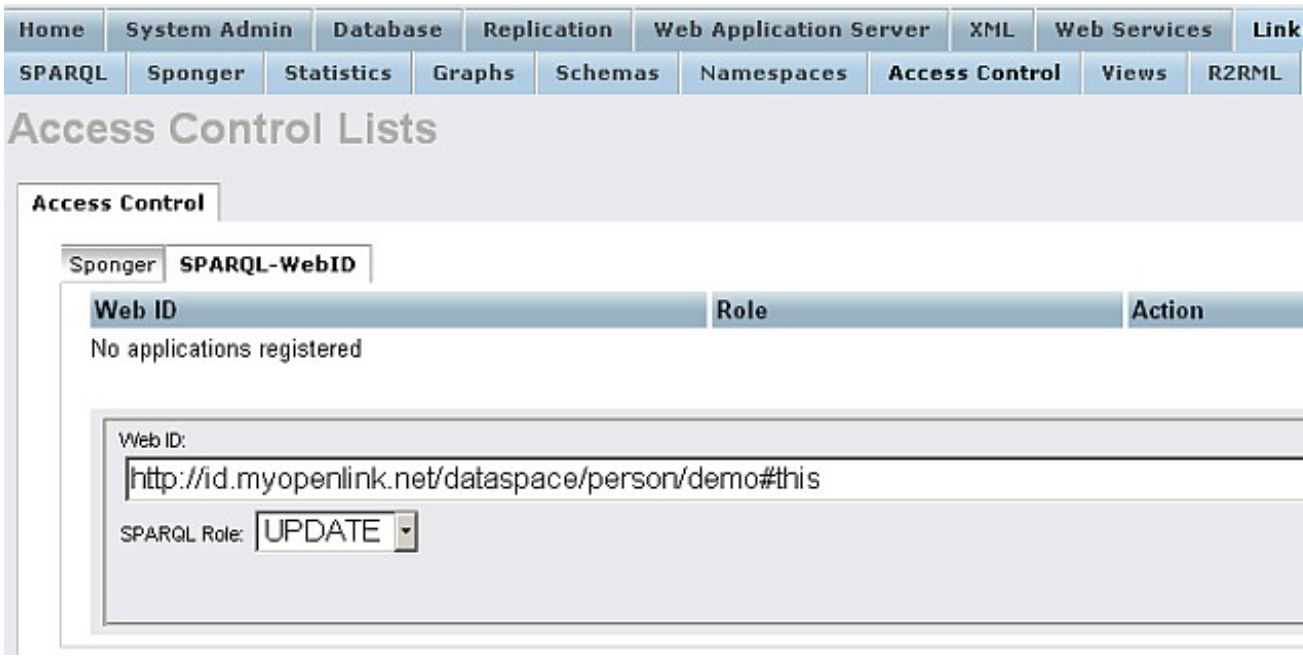
      ```
      http://id.myopenlink.net/dataspace/person/demo#this
      ```

   b. Select "SPARQL Role": "

      UPDATE

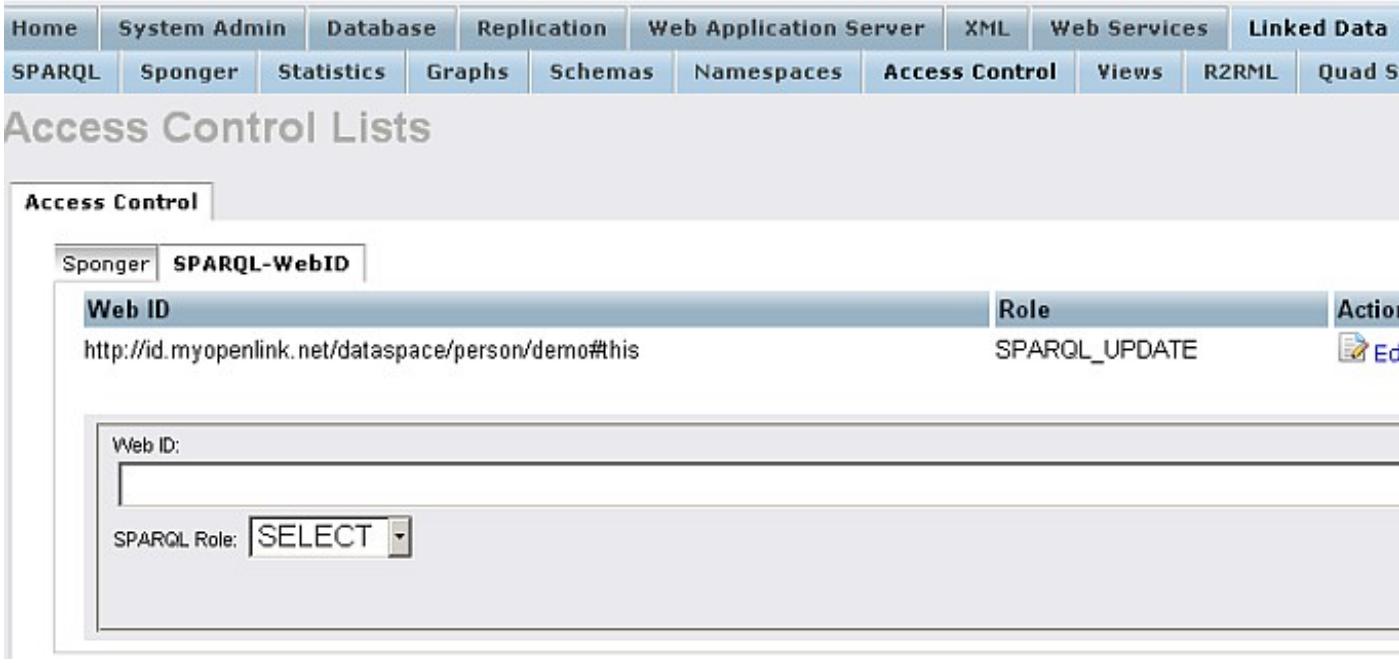
      ".

Figure 16.46. Conductor SPARQL-WebID



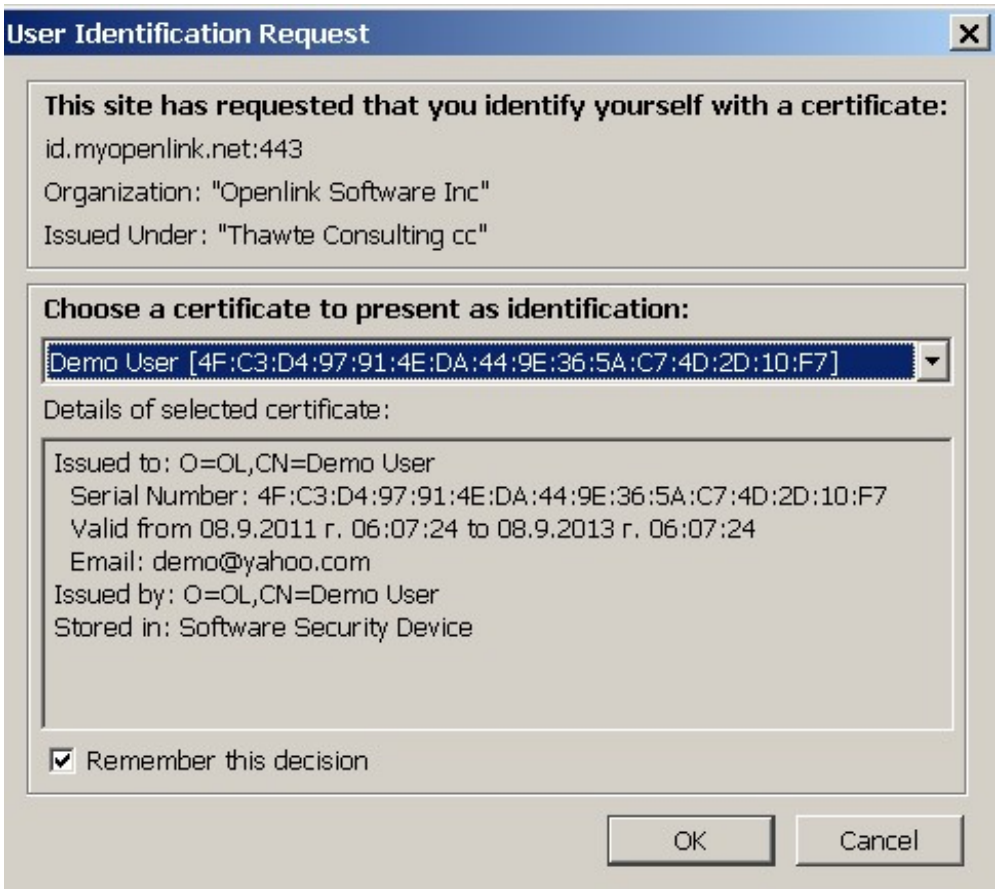
6. Click the "Register" button.
7. The WebID Protocol ACL will be created:

Figure 16.47. Conductor SPARQL-WebID



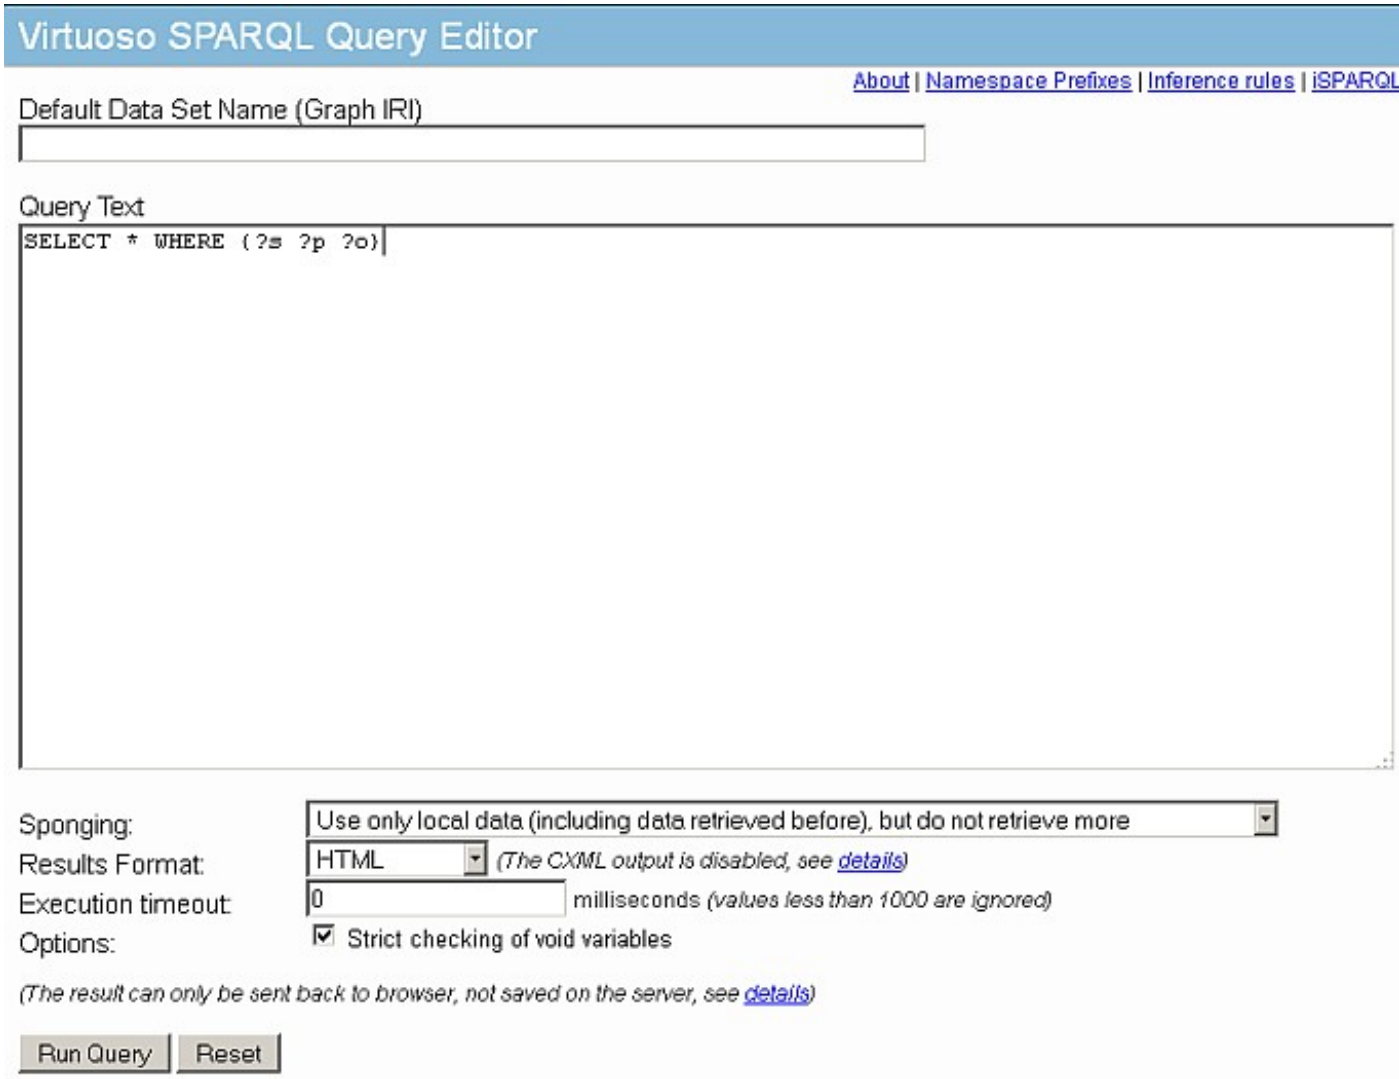
8. Go to the SPARQL-WebID endpoint, https://<cname>:<port>/sparql-webid, where <cname>:<port> are replaced by your local server values.
9. Select the user's certificate:

Figure 16.48. Conductor SPARQL-WebID



10. The SPARQL Query UI will be displayed:

Figure 16.49. Conductor SPARQL-WebID



11. Execute the query:

```
INSERT INTO GRAPH <http://example.com> {
  <s1> <p1> <o1> .
  <s2> <p2> <o2> .
  <s3> <p3> <o3>
}
```

Figure 16.50. Conductor SPARQL-WebID

Figure 16.51. Conductor SPARQL-WebID

callret-0
Insert into <http://mytest.com>, 3 (or less) triples -- done

Note: If the SPARQL Role "Sponge" is set instead, in order to be able to execute DELETE/INSERT statements over the protected SPARQL Endpoint, the following grants need to be performed for the user, associated with the WebID ACL Role:

```
grant execute on DB.DBA.SPARQL_INSERT_DICT_CONTENT to "demo";
grant execute on DB.DBA.SPARQL_DELETE_DICT_CONTENT to "demo";
```

Example usage of deleting Triple Patterns that are Not Scoped to a Named Graph

Presuming this triple exists in one or more graphs in the store:

```
{
  <http://kingsley.idehen.net/dataspace/person/kidehen#this>
    <http://xmlns.com/foaf/0.1/knows>
      <http://id.myopenlink.net/dataspace/person/KingsleyUyiIdehen#this>
}
```

The SQL query below will delete that triple from all graphs in the store:

```
DELETE
  FROM DB.DBA.RDF_QUAD
```

```
 WHERE p = iri_to_id
             ('http://xmlns.com/foaf/0.1/knows')
   AND s = iri_to_id
             ('http://kingsley.idehen.net/dataspace/person/kidehen#this')
   AND o = iri_to_id
             ('http://id.myopenlink.net/dataspace/person/KingsleyUyiIdehen#this')
;
```

According to SPARQL 1.1 Update , the FROM clause which scopes the query to a single graph is optional. Thus, the SQL query above can be rewritten to the SPARQL query below, again deleting the matching triple from all graphs in the store:

```
DELETE
  {
    GRAPH ?g
      {
        <http://kingsley.idehen.net/dataspace/person/kidehen#this>
          <http://xmlns.com/foaf/0.1/knows>
            <http://id.myopenlink.net/dataspace/person/KingsleyUyiIdehen#this>
      }
  }
WHERE
  {
    GRAPH ?g
      {
        <http://kingsley.idehen.net/dataspace/person/kidehen#this>
          <http://xmlns.com/foaf/0.1/knows>
            <http://id.myopenlink.net/dataspace/person/KingsleyUyiIdehen#this>
      }
  }
```

Example usage of deleting triples containing blank nodes

There are two ways to delete a particular blank node:

1. To refer to it via some properties or:
2. To convert it to it's internal "serial number", a long integer, and back.

Assume the following sample scenario:

1. Clear the graph:

```
SPARQL CLEAR GRAPH <http://sample/>;

Done. -- 4 msec.
```

2. Insert three blank nodes with two related triples each:

```
SPARQL
  INSERT IN GRAPH <http://sample/>
    {
      [] <p> <o1a> , <o1b> .
      [] <p> <o2a> , <o2b> .
      [] <p> <o3a> , <o3b>
    }

Done. -- 15 msec.
```

3. Delete one pair of triples:

```
SPARQL WITH <http://sample/>
  DELETE { ?s ?p ?o }
  WHERE
    {
      ?s ?p ?o ;
      <p> <o1a> .
    }

Done. -- 7 msec.
```

4. Ensure that we still have two bnodes, two triple per bnode:

```
SPARQL
```

```
  SELECT *
  FROM <http://sample/>
  WHERE
    {
      ?s ?p ?o
    }
s               p       o
VARCHAR         VARCHAR VARCHAR
_______________

nodeID://b10006 p       o3a
nodeID://b10006 p       o3b
nodeID://b10007 p       o2a
nodeID://b10007 p       o2b

4 Rows. -- 4 msec.
```

6. Each bnode, as well as any "named" node, is identified internally as an integer:

```
SPARQL
  SELECT (<LONG::bif:iri_id_num>(?s)) AS ?s_num, ?p, ?o
  FROM <http://sample/>
  WHERE
    {
      ?s ?p ?o
    };
s_num                p       o
INTEGER              VARCHAR VARCHAR
_____________________________

4611686018427397910  p       o3a
4611686018427397910  p       o3b
4611686018427397911  p       o2a
4611686018427397911  p       o2b

4 Rows. -- 5 msec.
```

7. The integer can be converted back to internal identifier. Say, here we try to delete a triple that does not exist (even if the ID integer is valid):

```
SPARQL
  DELETE FROM <http://sample/>
    {
      `bif:iri_id_from_num(4611686018427397911)` <p> <o3a>
    };

Done. -- 5 msec.
```

8. Should have no effect, because the "46..11" IRI has <o2a> and <o2b>, and was not requested <o3a>:

```
SPARQL
  SELECT *
  FROM <http://sample/>
  WHERE
    {
      ?s ?p ?o
    };
s               p        o
VARCHAR         VARCHAR  VARCHAR
_______________

nodeID://b10006 p        o3a
nodeID://b10006 p        o3b
nodeID://b10007 p        o2a
nodeID://b10007 p        o2b

4 Rows. -- 5 msec.
```

9. Now let's try to delete a triple that does actually exist. Note the use of backquotes to insert an expression into template:

```
SPARQL
  DELETE FROM <http://sample/>
    {
      `bif:iri_id_from_num(4611686018427397911)` <p> <o2a>
    };
```

```
Done. -- 4 msec.
```

10. So there's an effect:

```
SPARQL
  SELECT *
  FROM <http://sample/>
  WHERE
    {
      ?s ?p ?o
    };
s                 p        o
VARCHAR           VARCHAR  VARCHAR
_________________

nodeID://b10006   p        o3a
nodeID://b10006   p        o3b
nodeID://b10007   p        o2b

3 Rows. -- 2 msec.
```

11. Now delete everything related to `nodeID://b10006` subject:

```
SPARQL
  WITH <http://sample/>
  DELETE
    {
      ?s ?p ?o
    }
  WHERE
    {
      ?s ?p ?o .
      FILTER (?s = bif:iri_id_from_num(4611686018427397910))
    };

Done. -- 18 msec.
```

12. Three minus two gives one triple remaining:

```
SQL> SPARQL
  SELECT *
  FROM <http://sample/>
  WHERE
    {
      ?s ?p ?o
    };
s                 p        o
VARCHAR           VARCHAR  VARCHAR
_________________

nodeID://b10007   p        o2b

1 Rows. -- 4 msec.
```

Note : IDs of bnodes will vary from server to server and even from run to run on the same server, so the application should identify bnodes by properties before doing `bif:iri_id_XXX` tricks.

Example usage of expressions inside CONSTRUCT, INSERT and DELETE {...} Templates

When one wants to use expressions inside CONSTRUCT {...}, INSERT {...} or DELETE {...} construction templates, the expressions should be in back-quotes i.e:

```
`expression`
```

What?

How to construct RDF triples via SPARQL CONSTRUCT queries that include expressions.

Why?

The are times when you need to post-process existing RDF triples en route to creating enhanced data views. For instance, enhancing the literal values associated with annotation properties such as rdfs:label and rdfs:comment .

Why?

Here some SPARQL 1.1 Update Language examples showcasing how this is achieved using Virtuoso.

Example usage of expression inside CONSTRUCT

```
CONSTRUCT
  {
    ?inst  rdfs:label `bif:concat ( ?inst_label,
                                    " Instance with up to ",

16.3.3. Business Intelligence Extensions for SPARQL

Virtuoso extends SPARQL with expressions in results, subqueries, aggregates and grouping. These extensions allow a straightforward translation of arbitrary SQL queries to SPARQL. This extension is called "SPARQL BI", because the primary objective is to match needs of Business Intelligence. The extended features apply equally to querying physical quads or relational tables mapped through Linked Data Views.

Note

In this section, many examples use the TPC-H namespace. You may test them on your local demo database. They use data from the TPC-H dataset that is mapped into a graph with an IRI of the form http://example.com/tpch. When testing, you should replace the fake host name "example.com" with the host name of your own installation verbatim, that is as specified

Note

in the "DefaultHost" parameter in the [URIQA] section of the Virtuoso configuration file.

Aggregates in SPARQL

Virtuoso extends SPARQL with SQL like aggregate and "group by" functionality. This functionality is also available by embedding SPARQL text inside SQL, but the SPARQL extension syntax has the benefit of also working over the SPARQL protocol and of looking more SPARQL-like.

The supported aggregates are *COUNT* , *MIN* , *MAX* , *AVG* and *SUM* . These can take an optional *DISTINCT* keyword. These are permitted only in the selection part of a select query. If a selection list consists of a mix of variables and aggregates, the non-aggregate selected items are considered to be grouping columns and a *GROUP BY* over them is implicitly added at the end of the generated SQL query. Virtuoso also supports explicit syntax for *GROUP BY* , *ORDER BY* , *LIMIT* and *OFFSET* . There is no explicit syntax for *HAVING* in Virtuoso SPARQL.

If a selection consists of aggregates exclusively, the result set has one row with the values of the aggregates. If there are aggregates and variables in the selection, the result set has as many rows as there are distinct combinations of the variables; the aggregates are then calculated over each such distinct combination, as if there were a SQL GROUP BY over all non-aggregates. The implicit grouping pays attention to all subexpressions in the return list; say, if a result column expression is `(?x * max (?y))` then `?y` is aggregated and `?x` is not so it is grouped by ?x. This also means that if a result column expression is `(bif:year (?shipdate))` then a group is made for each distinct `?shipdate` , i.e. up to 366 groups for each distinct year. If you need one group per year, write explicit `GROUP BY (bif:year (?shipdate))` .

With the count aggregate the argument may be either * , meaning counting all rows, or a variable name, meaning counting all the rows where this variable is bound. If there is no implicit *GROUP BY* , there can be an optional *DISTINCT* keyword before the variable that is the argument of an aggregate.

There is a special syntax for counting distinct combinations of selected variables. This is:

```
SELECT COUNT DISTINCT ?v1 ... ?vn
  FROM ....
```

User-defined aggregate functions are not supported in current version of the SPARQL compiler.

Path Expressions

Virtuoso has support for paths consisting of dereferencing properties in SPARQL. Virtuoso allows simple paths in expressions and has a separate feature for transitivity:

- S+>P: for "one or many values of P of S"
- S*>P: for "zero or many values of P of S", so *> may form a LEFT OUTER JOIN whereas +> forms an INNER JOIN.
- S|>P: is reserved for potential "single value of P of S or an error if there are many values"

If this property is set (for example by an Linked Data View) then +> should be used.

Simple Example

```
SELECT ?f+>foaf:name ?f|>foaf:mbox WHERE { ?x foaf:name "Alice" . ?x foaf:knows ?f . FILTER (?f+>foaf:nam
```

means:

```
SELECT ?fname ?mbox
WHERE
  {
    ?x foaf:knows ?f .
    ?x foaf:knows ?f .
    OPTIONAL {?f foaf:mbox ?mbox} .
    ?f foaf:name ?fname .
    ?x foaf:name "Alice" .
    ?x foaf:knows ?f2 .
    ?f2 foaf:name "John" .
  }
```

Other Examples

```

Examples

Example for count of physical triples in http://mygraph.com

```
SPARQL
SELECT COUNT (*)
  FROM <http://mygraph.com>
 WHERE {?s ?p ?o}
```

Example for count of O's for each distinct P

```
SPARQL define input:inference "http://mygraph.com"
SELECT ?p COUNT (?o)
  FROM <http://mygraph.com>
 WHERE {?s ?p ?o}
```

Example for count of triples, including inferred triples and the count of distinct O values

```
SPARQL define input:inference "http://mygraph.com"
SELECT COUNT (?p) COUNT (?o) COUNT (DISTINCT ?o)
 FROM <http://mygraph.com>
WHERE {?s ?p ?o}
```

Example for get number of distinct bindings of ?s ?p ?o

```
SPARQL define input:inference "http://mygraph.com"
SELECT count distinct ?s ?p ?o
  FROM <http://mygraph.com>
 WHERE {?s ?p ?o}
```

Example for get counts and total prices of ordered items, grouped by item status

```
SPARQL
prefix tpch: <http://www.openlinksw.com/schemas/tpch#>
SELECT ?status count(*) sum(?extendedprice)
FROM <http://localhost.localdomain:8310/tpch>
WHERE {
    ?l a tpch:lineitem ;
      tpch:lineextendedprice ?extendedprice ;
      tpch:linestatus ?status .
  }
```

Example for get counts and total prices of ordered items, grouped by item status

Example: A dataset of people, some duplicated

Suppose there is a dataset with many people, some of them sharing the same name. To list them we would, ideally, execute the query:

```
SPARQL
SELECT DISTINCT
 (?name) ?person ?mail
 WHERE {
   ?person rdf:type foaf:Person .
   ?person foaf:name ?name .
   ?person foaf:mbox_sha1sum ?mail
 }
```

Unfortunately, the facility to apply DISTINCT to a part of the result set row (i.e. to ?name) does not currently exist. (Although the above form is permitted, it's interpreted as being identical to 'SELECT DISTINCT ?name, ?person, ?mail WHERE ...') If there's demand for such a feature then we may introduce an aggregate called, say, SPECIMEN, that will return the very first of the aggregated values. e.g.:

```
SPARQL
SELECT ?name (specimen(?person)) (specimen(?mail))
WHERE
  {
    ?person rdf:type foaf:Person .
    ?person foaf:name ?name .
    ?person foaf:mbox_sha1sum ?mail
  }
```

As a workaround to this limitation, the MIN aggregate can be used, provided duplicates are few and there's no requirement that ?person should correspond to ?mail (i.e. the result should contain some person node and some mail node but they don't have to be connected by foaf:mbox_sha1sum):

```
SPARQL
SELECT ?name (min(?person)) (min(?mail))
WHERE
  {
    ?person rdf:type foaf:Person .
    ?person foaf:name ?name .
    ?person foaf:mbox_sha1sum ?mail
  }
```

Otherwise, a complicated query is needed:

```
SPARQL
SELECT
 ?name
 ((SELECT (min (?person3))
     WHERE {
         ?person3 rdf:type foaf:Person .
         ?person3 foaf:name ?name .
         ?person3 foaf:mbox_sha1sum ?mail } )) as ?person
 ?mail
 WHERE {
     { SELECT distinct ?name
       WHERE {
           ?person1 rdf:type foaf:Person .
           ?person1 foaf:name ?name .
           ?person1 foaf:mbox_sha1sum ?mail1 } }
     { SELECT ?name (min(?mail2)) as ?mail
       WHERE {
           ?person2 rdf:type foaf:Person .
           ?person2 foaf:name ?name .
           ?person2 foaf:mbox_sha1sum ?mail2 } }
 }
```

Example quering dbpedia

The following example demonstrate how to query dbpedia. Suppose there is local onotlogy, which has a datatype property hasLocation with a string containing city names. The query below finds which of those cities are in dbpedia:

```
SPARQL
PREFIX dbpprop: <http://dbpedia.org/property/>
PREFIX dbo: <http://dbpedia.org/ontology/>
PREFIX vocab:<http://myexample.com/localOntology.rdf>
PREFIX dbpedia: <http://dbpedia.org/>
PREFIX dbpres: <http://dbpedia.org/resource/>
SELECT ?city
WHERE
  {
    ?sub :location ?city .
    FILTER(bif:exists(( ASK { ?subdb a dbo:City . ?subdb dbpprop:officialName ?city })))
  }
```

Example for MAX with HAVING and GROUP BY

```
## Example "Find which town or city in
## the UK has the largest proportion of students.

PREFIX dbpedia-owl: <http://dbpedia.org/ontology/>
PREFIX dbpedia-owl-uni: <http://dbpedia.org/ontology/University/>
PREFIX dbpedia-owl-inst: <http://dbpedia.org/ontology/EducationalInstitution/>

SELECT ?town COUNT(?uni)
       ?pgrad ?ugrad
       MAX(?population)
       ( ((?pgrad+?ugrad)/ MAX(?population))*100 ) AS ?percentage
WHERE
  {
    ?uni dbpedia-owl-inst:country dbpedia:United_Kingdom ;
                         dbpedia-owl-uni:postgrad ?pgrad ;
                        dbpedia-owl-uni:undergrad ?ugrad ;
                             dbpedia-owl-inst:city ?town .
    OPTIONAL
        {
          ?town dbpedia-owl:populationTotal ?population .
          FILTER (?population > 0 )
        }
  }
GROUP BY ?town ?pgrad ?ugrad
HAVING ( ( ( (?pgrad+?ugrad)/ MAX(?population) )*100 ) > 0 )
ORDER BY DESC 6
```

Example Aggregating Distance Values Over Years

The following example demonstrate how to aggregate Distance Values Over Years:

First we insert some data in a graph with name for ex. <urn:dates:distances>:

```
SQL> SPARQL INSERT INTO GRAPH <urn:dates:distances>
  {
    <:a1> <http://purl.org/dc/elements/1.1/date> <2010-12-23T00:00:00> .
    <:a1> <http://linkedgeodata.org/vocabulary#distance> <0.955218675> .
    <:a2> <http://purl.org/dc/elements/1.1/date> <2010-12-24T00:00:00> .
    <:a2> <http://linkedgeodata.org/vocabulary#distance> <0.798155989> .
    <:a3> <http://purl.org/dc/elements/1.1/date> <2010-12-25T00:00:00> .
    <:a3> <http://linkedgeodata.org/vocabulary#distance> <0.064686628> .
    <:a4> <http://purl.org/dc/elements/1.1/date> <2010-12-26T00:00:00> .
    <:a4> <http://linkedgeodata.org/vocabulary#distance> <0.279800332> .
    <:a5> <http://purl.org/dc/elements/1.1/date> <2010-12-27T00:00:00> .
    <:a5> <http://linkedgeodata.org/vocabulary#distance> <0.651255995> .

Note on Aggregates and Inference

Inferencing is added to a SPARQL query only for those variables whose value is actually used. Thus,

```
SELECT COUNT (*)
 FROM <http://mygraph.com>
WHERE {?s ?p ?o}
```

will not return inferred values since s, p, and o are not actually used. In contrast,

```
SPARQL
SELECT COUNT (?s) COUNT (?p) COUNT (?o)
 FROM <http://mygraph.com>
WHERE {?s ?p ?o}
```

will also return all the inferred triples.

Note: This difference in behaviour may lead to confusion and will, therefore, likely be altered in the future.

Pointer Operator (*+>* and **>*)

When expressions occur in result sets, many variables are often introduced only for the purpose of passing a value from a triple pattern to the result expression. This is inconvenient because many triple patterns are trivial. The presence of large numbers of variable names masks "interesting" variables that are used in more than once in pattern and which establish logical relationships between different parts of the query. As a solution we introduce pointer operators.

The +> (pointer) operator allows referring to a property value without naming it as a variable and explicitly writing a triple pattern. We can shorten the example above to:

```
SPARQL
prefix tpch: <http://www.openlinksw.com/schemas/tpch#>
SELECT ?l+>tpch:linestatus count(*) sum(?l+>tpch:lineextendedprice)
FROM <http://localhost.localdomain:8310/tpch>
WHERE { ?l a tpch:lineitem }
```

The *?subject+>propertyname* notation is equivalent to having a triple pattern *?subject propertyname ?aux_var* binding an auxiliary variable to the mentioned property of the subject, within the group pattern enclosing the reference. For a SELECT, the enclosing group pattern is considered to be the top level pattern of the where clause or, in the event of a union, the top level of each term of the union. Each distinct pointer adds exactly one triple pattern to the enclosing group pattern. Multiple uses of +> with the same arguments do not each add a triple pattern. (Having multiple copies of an identical pattern might lead to changes in cardinality if multiple input graphs were being considered. If a lineitem had multiple discounts or extended prices, then we would get the cartesian product of both.)

If a property referenced via +> is absent, the variable on the left side of the operator is not bound in the enclosing group pattern because it should be bound in all triple patterns where it appears as a field, including implicitly added patterns.

The *?subject*>propertyname* notation is introduced in order to access optional property values. It adds an OPTIONAL group *OPTIONAL { ?subject propertyname ?aux_var }* , not a plain triple pattern, so the binding of ?subject is not changed even if the object variable is not bound. If the property is set for all subjects in question then the results of *> and +> are the same. All other

things being equal, the +> operator produces better SQL code than *> so use *> only when it is really needed.

Subqueries in SPARQL

Pure SPARQL does not allow binding a value that is not retrieved through a triple pattern. We lift this restriction by allowing expressions in the result set and providing names for result columns. We also allow a SPARQL SELECT statement to appear in another SPARQL statement in any place where a group pattern may appear. The names of the result columns form the names of the variables bound, using values from the returned rows. This resembles derived tables in SQL.

For instance, the following statement finds the prices of the 1000 order lines with the biggest discounts:

```
SPARQL
define sql:signal-void-variables 1
prefix tpch: <http://www.openlinksw.com/schemas/tpch#>
SELECT ?line ?discount (?extendedprice * (1 - ?discount)) as ?finalprice
FROM <http://localhost.localdomain:8310/tpch>
WHERE
  {
    ?line a tpch:lineitem ;
    tpch:lineextendedprice ?extendedprice ;
    tpch:linediscount ?discount .
  }
ORDER BY DESC (?extendedprice * ?discount)
LIMIT 1000
```

After ensuring that this query works correctly, we can use it to answer more complex questions. Imagine that we want to find out how big the customers are who have received the biggest discounts.

```
SPARQL
define sql:signal-void-variables 1
prefix tpch: <http://www.openlinksw.com/schemas/tpch#>
SELECT ?cust sum(?extendedprice2 * (1 - ?discount2)) max (?bigdiscount)
FROM <http://localhost.localdomain:8310/tpch>
WHERE
  {
    {
      SELECT ?line (?extendedprice * ?discount) as ?bigdiscount
      WHERE {
        ?line a tpch:lineitem ;
          tpch:lineextendedprice ?extendedprice ;
          tpch:linediscount ?discount . }
      ORDER BY DESC (?extendedprice * ?discount)
      LIMIT 1000
    }
    ?line tpch:has_order ?order .
    ?order tpch:has_customer ?cust .
    ?cust tpch:customer_of ?order2 .
    ?order2 tpch:order_of ?line2 .
    ?line2 tpch:lineextendedprice ?extendedprice2 ;
      tpch:linediscount ?discount2 .
  }
ORDER BY (SUM(?extendedprice2 * (1 - ?discount2)) / MAX (?bigdiscount))
```

The inner select finds the 1000 biggest (in absolute value) discounts and their order lines. For each line we find orders of it, and the customer. For each customer found, we find all the orders he made and all the lines of each of the orders (variable ?line2).

Note that the inner select does not contain FROM clauses. It is not required because the inner select inherits the access permissions of all the outer queries. It is also important to note that the internal variable bindings of the subquery are not visible in the outer query; only the result set variables are bound. Similarly, variables bound in the outer query are not accessible to the subquery.

Note also the declaration *define sql:signal-void-variables 1* that forces the SPARQL compiler to signal errors if some variables cannot be bound due to misspelt names or attempts to make joins across disjoint domains. These diagnostics are especially important when the query is long.

Expressions in Triple Patterns

In addition to expressions in filters and result sets, Virtuoso allows the use of expressions in triples of a CONSTRUCT pattern or WHERE pattern - an expression can be used instead of a constant or a variable name for a subject, predicate or object. When used in this context, the expression is surrounded by backquotes.

Example: With a WHERE Clause:

The following example returns all the distinct 'fragment' parts of all subjects in all graphs that have some predicate whose value is equal to 2+2.

```
SQL>SPARQL SELECT distinct (bif:subseq (?s, bif:strchr (?s, '#')))
   WHERE {
     graph ?g {
       ?s ?p `2+2` .
       FILTER (! bif:isnull (bif:strchr (?s, '#') ) )
     } };

callret
VARCHAR
----------
#four
```

Inside a WHERE part, every expression in a triple pattern is replaced with new variable and a filter expression is added to the enclosing group. The new filter is an equality of the new variable and the expression. Hence the sample above is identical to:

```
SPARQL
SELECT distinct (bif:subseq (?s, bif:strchr (?s, '#')))
   WHERE {
     graph ?g {
       ?s ?p ?newvariable .
       FILTER (! bif:isnull (bif:strchr (?s, '#') ) )
       FILTER (?newvariable = (2+2)) .
     } }
```

Example: With CONSTRUCT

```
CONSTRUCT {
  <http://bio2rdf.org/interpro:IPR000181>
<http://bio2rdf.org/ns/bio2rdf#hasLinkCount>
`(SELECT (count(?s)) as ?countS
   WHERE { ?s ?p <http://bio2rdf.org/interpro:IPR000181> })` }
WHERE { ?s1 ?p1 ?o1 } limit 1
```

The result should be:

```
<http://bio2rdf.org/interpro:IPR000181> <http://bio2rdf.org/ns/bio2rdf#hasLinkCount> "0"^^<http://www.w3.
```

Example: Inserting into a graph using an expression

```
SQL>SPARQL insert into graph <http://MyNewGraph.com/> {
<http://bio2rdf.org/interpro:IPR000181>
<http://bio2rdf.org/ns/bio2rdf#hasLinkCount>
  `(SELECT (count(?s)) as ?countS
    WHERE { ?s ?p <http://bio2rdf.org/interpro:IPR000181> })` }
 WHERE { ?s1 ?p1 ?o1 } limit 1  ;

callret-0
VARCHAR
_______________________________________________________________________________

Insert into <http://MyNewGraph.com/>, 1 triples -- done

1 Rows. -- 30 msec.
```

16.4. RDF Graphs Security

16.4.1. RDF Graph Groups

In some cases, the data-set of a SPARQL query is not known at compile time. It is possible to pass IRIs of source graphs via parameters, but the method is not perfect as:

- not all protocols are suitable for parameter passing, and no one is an interoperable standard
- passing list of IRIs as a parameter will usually require the use of Virtuoso-specific functions in the text of SPARQL query, that's bad for some query builders.
- lack of knowledge about actual graphs may damage query optimization

It would be nice to create named lists of graphs and a clause like "SELECT from all graph names of the specified list". *"Graph groups"* serve for this purpose. That is Virtuoso-specific SPARQL extension that let create a named list of IRIs such that if name of the list is used in *FROM* clause like *IRI* of default graph then it is equivalent to list of *FROM* clauses, one clause for each item of the list.

Internally, descriptions of graph groups are kept in two tables: *Table of graph groups:*

```
create table DB.DBA.RDF_GRAPH_GROUP (
  RGG_IID IRI_ID not null primary key,  -- IRI ID of RGG_IRI field
  RGG_IRI varchar not null,             -- Name of the group
  RGG_MEMBER_PATTERN varchar,           -- Member IRI pattern
  RGG_COMMENT varchar                   -- Comment
  )
create index RDF_GRAPH_GROUP_IRI on DB.DBA.RDF_GRAPH_GROUP (RGG_IRI)
;
```

Table of contents of groups:

```
create table DB.DBA.RDF_GRAPH_GROUP_MEMBER (
  RGGM_GROUP_IID IRI_ID not null,       -- IRI_ID of the group
  RGGM_MEMBER_IID IRI_ID not null,      -- IRI_ID of the group member
  primary key (RGGM_GROUP_IID, RGGM_MEMBER_IID)
  )
;
```

Fields *RGG_MEMBER_PATTERN* and *RGG_COMMENT* are not used by system internals but applications may wish to write their data there for future reference. *RGG_COMMENT* is supposed to be human-readable description of the group and *RGG_MEMBER_PATTERN* may be useful for functions that automatically add IRIs of a given graph to all graph groups such that the graph IRI string match *RGG_MEMBER_PATTERN* regexp pattern.

A dictionary of all groups and their members is cached in memory for fast access. Due to this reason, applications may read these tables and modify *RGG_MEMBER_PATTERN* and *RGG_COMMENT* if needed but not change other fields directly. The following API procedures makes changes in a safe way:

```
DB.DBA.RDF_GRAPH_GROUP_CREATE (
  in group_iri varchar,
  in quiet integer,
  in member_pattern varchar := null,
  in comment varchar := null)
```

That creates a new empty graph group. An error is signaled if the group exists already and quiet parameter is zero.

```
DB.DBA.RDF_GRAPH_GROUP_INS (in group_iri varchar, in memb_iri varchar)
DB.DBA.RDF_GRAPH_GROUP_DEL (in group_iri varchar, in memb_iri varchar)
```

These two are to add or remove member to an existing group. Double insert or removal of not a member will not signal errors, but missing group will.be signaled.

```
DB.DBA.RDF_GRAPH_GROUP_DROP (
  in group_iri varchar,
  in quiet integer)
```

That removes graph group. An error is signaled if the group did not exist before the call and quiet parameter is zero.

Graph groups are *"macro-expanded"* only in FROM clauses and have no effect on FROM NAMED or on GRAPH <IRI> {...} . Technically, it is not prohibited to use an IRI as both plain graph IRI and graph group IRI in one storage but this is confusing and is not recommended.

Graph groups can not be members of other graph groups, i.e. the IRI of a graph group can appear in the list of members of some group but it will be treated as plain graph IRI and will not cause recursive expansion of groups.

16.4.2. NOT FROM and NOT FROM NAMED Clauses

In addition to standard FROM and FROM NAMED clauses, Virtuoso extends SPARQL with NOT FROM and NOT FROM NAMED clauses of "opposite" meaning.

```
SELECT ... NOT FROM <x> ... WHERE {...}
```

means "SELECT FROM other graphs, but not from the given one". This is especially useful because NOT FROM supports graph groups (NOT FROM NAMED supports only plain graphs). So if

```
<http://example.com/users/private>
```

is a graph group of all graphs with confidential data about users then

```
SELECT * NOT FROM <http://example.com/users/private> WHERE {...}
```

will be restricted only to insecure data.

NOT FROM overrides any FROM and NOT FROM NAMED overrides any FROM NAMED, the order of clauses in the query text is not important.

The SPARQL web service endpoint configuration string may contain pragmas *input:default-graph-exclude* and *input:named-graph-exclude* that become equivalent to NOT FROM and NOT FROM NAMED clauses like *input:default-graph-uri* and *input:named-graph-uri* mimics FROM and FROM NAMED.

16.4.3. Graph-Level Security

Virtuoso supports graph-level security for "physical" RDF storage. That is somewhat similar to table access permissions in SQL. However, the difference between SPARQL and SQL data models results in totally different style of security administration. In SQL, when new application is installed it comes with its own set of tables and every query in its code explicitly specifies tables in use. Security restrictions of two applications interfere only if applications knows each other and are supposedly designed to cooperate. It is possible to write an application that will get list of available tables and retrieve data from any given table but that is a special case and it usually requires DBA privileges.

In SPARQL, data of different applications shares one table and the query language allows to select data of all applications at once. This feature makes SPARQL convenient for cross-application data integration. At the same time, that become a giant security hole if any sensitive data are stored.

A blind copying SQL security model to SPARQL domain would result in significant loss of performance or weak security or even both problems at the same time. That is why SPARQL model is made much more restrictive, even if it becomes inconvenient for some administration tasks.

Graph-level security does not replace traditional SQL security. A user should become member of appropriate group (`SPARQL_SELECT` , `SPARQL_SPONGE` or `SPARQL_UPDATE`) in order to start using its graph-level privileges.

16.4.4. Graph-Level Security and SQL

SPARQL-level graph security is sufficient for SPARQL client operating over HTTP. It is not sufficient for SQL clients due to the fact that graph level security is baked into the SPARQL compiler, not by an SQL compiler.

The Virtuoso SPARQL compiler analyzes the graph-level permissions of a user (an identity principal named using an identifier e.g., WebID or NetID). For each triple pattern or graph group pattern the compiler adds an implicit FILTER () that ensures that

appropriate privileges are granted on target named graphs to a given user. Ultimately, these FILTERs becomes part of the generated SQL code processed against the RDF_QUAD and related RDF data management system tables.

SQL users accessing Virtuoso via ODBC, JDBC, ADO.NET, and OLE-DB connections have the ability to execute arbitrary SQL code via stored procedures, subject to SQL level privileges on target Tables and Views which provides a point of vulnerability to the RDF system tables (RDF_QUAD and others). To close this vulnerability, the SQL compiler restricts SQL connection access, in regards to RDF system tables, to members of `the SPARQL_SELECT_RAW` group.

Note: `SPARQL_SELECT_RAW` group is a feature applicable to Virtuoso 7.5 or higher.

Graph-Level Security and SQL Usage Example

The following example demonstrates how to grant `SPARQL_SELECT_RAW` to a Virtuoso SQL user:

```
SQL> DB.DBA.USER_CREATE ('John', 'John');
Done. -- 0 msec.
SQL> GRANT SPARQL_SELECT to "John";
Done. -- 0 msec.
SQL> GRANT SPARQL_SELECT_RAW to "John";
Done. -- 0 msec.
```

16.4.5. Understanding Default Permissions

In relational database, default permissions are trivial. DBA is usually the only account that can access any table for both read and write. Making some table public or private does not affect applications that do not refer that table in the code. Tables are always created before making security restrictions on them.

Chances are very low that an application will unintentionally create some table and fill in with confidential data. There are no unauthenticated users, any client has some user ID and no one user is "default user" so permissions of any two users are always independent.

SPARQL access can be anonymous and graphs can be created during routine data manipulation. For anonymous user, only public resources are available. Thus "default permissions" on some or all graphs are actually permissions of "nobody" user, (the numeric ID of this user can be obtained by http_nobody_uid() function call). As a consequence, there's a strong need in "default permission" for a user, this is the only way to specify what to do with all graphs that does not exist now it might exist in some future.

An attempt to make default permissions wider than specific is always potential security hole in SPARQL, so this is strictly prohibited.

Four sorts of access are specified by four bits of an integer "permission bit-mask", plain old UNIX style:

- Bit 1 permits read access.
- Bit 2 permits write access via SPARUL and it's basically useless without bit 1 set.
- Bit 4 permits write access via "RDF sponge" methods and it's basically useless without bits 1 and 2 set.
- Bit 8 allows to obtain list of members of graph group; an IRI can be used as graph IRI and as graph group IRI at the same time so bit 8 can be freely combined with any of bits 1, 2 or 4.

Note that obtaining the list of members of a graph group does not grant any access permissions to triples from member graphs. It is quite safe to mix secure and public graphs in one graph group.

When a SPARQL query should check whether a given user have permission to access a given graph then the order of checks is as follows:

1. permissions of the user on the specific graph;
2. default permissions of the user on all graphs;
3. public permissions on the specific graph;
4. public permissions on all graphs

If no one above mentioned permission is set then the access is "read/write/sponge/list".

For "nobody" user, steps 3 and 4 become exact copies of steps 1 and 2 so they are skipped.

16.4.6. Initial Configuration of SPARQL Security

It is convenient to configure the RDF storage security by adding restrictions in the order inverse to the order of checks:

1. Step 1: Set public permissions on all graphs to the most restricted level of any application that will be installed. So if any single graph will be unreadable for public, then public permissions on all graphs should be set to 0 or 8.
2. Step 2: Public permissions on "insecure" graphs should be set. So if the database contains DBpedia or WordNet or some other data of Linking Open Data project then public permissions for that graphs may be set to 1.
3. Step3: Configure trusted users, such as administrative DBA-like accounts, and to specify their permissions on all graphs.
4. Step 4: Some additional right can be granted to some specific users on some specific graphs.

Note that there's no need to permit something to DBA itself, because DBA's default permissions are set automatically.

Configuring New User

1. Step 1: Grant SPARQL_SELECT, SPARQL_SPONGE or SPARQL_UPDATE to the user.
2. Step 2: Set user's permissions on all graphs.
3. Step 3: Grant rights on some specific graphs.

Example: Blogs and Resource Sharing

The following example demonstrates usage of the following functions:

- `DB.DBA.RDF_DEFAULT_USER_PERMS_SET (uname, permissions, set_private);`
- `DB.DBA.RDF_DEFAULT_USER_PERMS_DEL (uname, set_private);`
- `DB.DBA.RDF_GRAPH_USER_PERMS_SET (graph_iri, uname, permissions);`
- `DB.DBA.RDF_GRAPH_USER_PERMS_DEL (graph_iri, uname);`
- `DB.DBA.RDF_ALL_USER_PERMS_DEL (uname, uid);`

Consider a "groupware" application that let users create personal resources with access policies.

```
-- First, create few users, in alphabetical order.
SQL> DB.DBA.USER_CREATE ('Anna', 'Anna');
Done. -- 0 msec.
SQL> DB.DBA.USER_CREATE ('Brad', 'Brad');
Done. -- 0 msec.
SQL> DB.DBA.USER_CREATE ('Carl', 'Carl');
Done. -- 16 msec.
SQL> GRANT SPARQL_UPDATE to "Anna";
Done. -- 0 msec.
SQL> GRANT SPARQL_UPDATE to "Brad";
Done. -- 0 msec.
SQL> GRANT SPARQL_UPDATE to "Carl";
Done. -- 0 msec.

-- At least some data are supposed to be confidential, thus the whole storage becomes confidential.
SQL> DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('nobody', 0);
Done. -- 16 msec.

-- Moreover, no one of created users have access to all graphs (even for reading).
SQL> DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Anna', 0);
Done. -- 0 msec.
SQL> DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Brad', 0);
Done. -- 0 msec.
SQL> DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Carl', 0);
Done. -- 0 msec.

16.4.7. Application Callbacks for Graph Level Security

In some cases, different applications should provide different security for different users. Two SPARQL pragmas are provided for this purpose:

- Pragma sql:gs-app-callback is to specify Virtuoso/PL callback function that return permission bits for given graph.
- Pragma sql:gs-app-uid is to specify application-specific user ID that is some string that is passed to the callback "as is".

The name of callback is always DB.DBA.SPARQL_GS_APP_CALLBACK_nnn, where nnn is value of sql:gs-app-callback.

The callback is called only if the application has access to the graph in question so it may restrict the caller's account but not grant more permissions.

Example

Let user of application get full access to graphs whose IRIs contain user's name in path. In addition, let all of them permission to use all graph groups and let the "moderator" user read everything.

```
reconnect "dba";

create function DB.DBA.SPARQL_GS_APP_CALLBACK_TEST (in g_iid IRI_ID, in app_uid varchar) returns integer
{
  declare g_uri varchar;
-- A fake IRI ID #i0 is used to mention account's default permissions for all graphs.
  if (#i0 = g_iid)
    {
      if ('moderator' = app_uid)
        return 9; -- Moderator can read and list everything.
      return 8; -- Other users can list everything.
    }
  g_uri := id_to_iri (g_iid);
  if (strstr (g_uri, '/' || app_uid || '/'))
    return 15; -- User has full access to "his" graph.
  return 8; -- User can list any given graph group.
}
;

SPARQL
define sql:gs-app-callback "TEST"
define sql:gs-app-uid "Anna"
SELECT ?g ?s WHERE { ?s <p> ?o }
;
```

16.4.8. Graph-level security and sponging

In some cases the sponged data contains private information for instances cartridges like Facebook, etc. To perform private sponging, Virtuoso offers *get:private* pragma:

```
define get:private ""
or
define get:private <graph_group_IRI>
```

When used for sponging graph X, it adjusts graph-level security of graph X (and of graph_group_IRI, if specified) so that X becomes a privately accessible graph of the user who sponges the X and if graph_group_IRI is specified then X becomes accessible to users that can access graph_group_IRI with permissions like permissions they have on graph_group_IRI.

The exact rules are as following:

- If graph is virtrdf: then an error is signaled.
- If graph name is an IRI of handshaked web service endpoint or "public IRI" of a handshaked web service endpoint then an error is signaled.
- If access is public by default even for private graphs then an error is signaled and sponging is not tried.
- If default is "no access" but someone (other than current user) has specifically granted read access to the graph in question AND current user is not dba AND current user has no bit 32 permission on this graph then an error is signaled.
- If read access is public by default for world and disabled for private graphs then the graph to be sponged is added to the group of private graphs.
- If current user is not DBA, current user gets granted read+write+sponge+admin access to the graph to be sponged. In addition, current user gets special permission bit 32, indicating that the graph is made by private sponge of this specific user.
- If the value of get:private is an IRI then:
    - The IRI is supposed to be an IRI of "plain" graph group, error is signaled in case of nonexising graph group, group of private graphs or group of graphs to be replicated.
    - The graph is added to that group
    - Each non-dba user that can get list of files of the group will get permissions for the loaded graph equal to permissions they have on graph group minus "list" permission.

Example Performing Sponging on a entirely confidential database using get:private pragma

The following example demonstrates how private sponging using get:private pragma works for entirely confidential database.

Note : Please take in mind that the steps from below will change the security of any existing database, thus the example scenario should be performed on a empty db.

1. Create few users in alphabetical order:

```
DB.DBA.USER_CREATE ('Anna', 'Anna');
DB.DBA.USER_CREATE ('Brad', 'Brad');
DB.DBA.USER_CREATE ('Carl', 'Carl');
```

2. Set to Anna, Brad and Carl SPARQL SELECT, UPDATE and SPONGE permissions:

```
grant SPARQL_SELECT to "Anna";
grant SPARQL_SELECT to "Brad";
grant SPARQL_SELECT to "Carl";

grant SPARQL_UPDATE to "Anna";
grant SPARQL_UPDATE to "Brad";
grant SPARQL_UPDATE to "Carl";

grant SPARQL_SPONGE to "Anna";
grant SPARQL_SPONGE to "Brad";
grant SPARQL_SPONGE to "Carl";
```

3. Set specific privileges to given graphs for specifics users: Catering for the fact that some datasets are supposed to be confidential, thus the whole quad storage is set to confidential. Then specific privileges can be assigned to specific graphs for specific users:

```
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('nobody', 0);
```

4. Set specific privileges: assuming for users Anna, Brad and Carl none of these individual has any kind of global access to graphs:

```
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Anna', 0);
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Brad', 0);
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Carl', 0);
```

5. Assuming the following four sorts of access that are specified by four bits of an integer "permission bit-mask", following plain old UNIX style:

    - Bit 1 permits read access.
    - Bit 2 permits write access via SPARUL and is basically useless without bit 1 set.
    - Bit 4 permits write access via "RDF Network Resource Fetch" methods and is basically useless without bits 1 and 2 set.
    - Bit 8 allows retrieval of the list of members of a graph group. An IRI can be used as a graph IRI and as a graph group IRI at the same time, so bit 8 can be freely combined with any of bits 1, 2 or 4.
    - In the statements from below should be considered:
        - "15 = 8+4+2+1" -- i.e. combining all the four sorts of access FROM above
        - "9 = 8 + 1" -- i.e. read access + access to retrieve the list of members for a given graph group

```
-- Create Graph Group for Anna and set privileges:
DB.DBA.RDF_GRAPH_GROUP_CREATE ('urn:Anna:Sponged:Data', 1);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Anna:Sponged:Data', 'Anna', 15);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Anna:Sponged:Data', 'Brad', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Anna:Sponged:Data', 'Carl', 9);

-- Create Graph Group for Brad and set privileges:
DB.DBA.RDF_GRAPH_GROUP_CREATE ('urn:Brad:Sponged:Data', 1);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Brad:Sponged:Data', 'Anna', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Brad:Sponged:Data', 'Brad', 15);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Brad:Sponged:Data', 'Carl', 9);

-- Create Graph Group for Carl and set privileges:
DB.DBA.RDF_GRAPH_GROUP_CREATE ('urn:Carl:Sponged:Data', 1);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Carl:Sponged:Data', 'Anna', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Carl:Sponged:Data', 'Brad', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Carl:Sponged:Data', 'Carl', 15);
```

6. Examples with invalid graph group names:

a. Example with Non-existing Graph Group:

```
-- An error for non-existing Graph group <http://nosuch/> will be raised.

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <http://nosuch/>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

b. Example with "virtrdf:PrivateGraphs" graph group which is reserved for system usage:

```
-- An error for attempt to add a graph to special
-- graph group <http://www.openlinksw.com/schemas/virtrdf#PrivateGraphs> will be raised.

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private virtrdf:PrivateGraphs
  SELECT * FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

c. Example with "virtrdf:rdf_repl_graph_group" graph group which is reserved for system usage:

```
-- An error for attempt to add a graph to special
-- graph group <http://www.openlinksw.com/schemas/virtrdf#rdf_repl_graph_group> will be rai

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private virtrdf:rdf_repl_graph_group
  SELECT * FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

7. Examples to check Anna's sponging permissions on different graph groups:

a. Example for adding graph to Anna's graph group <urn:Anna:Sponged:Data>:

```
-- No error will be raised as Anna has the efficient rights for graph group <urn:Anna:Spong

reconnect "Anna";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Anna:Sponged:Data>
  SELECT *
  FROM <http://example.com/anna/>
  WHERE
    { ?s ?p ?o };
```

b. Example for adding graph to Brad's graph group <urn:Brad:Sponged:Data>:

```
-- An error will be raised because "Anna" has not enough rights on that group

reconnect "Anna";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Brad:Sponged:Data>
  SELECT * FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

c. Example for adding graph to Carl's graph group <urn:Carl:Sponged:Data>:

```
-- An error will be raised because "Anna" has not enough rights on that group

reconnect "Anna";
```

```
SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

8. Examples check Brad's sponging permissions on different graph groups:

   a. Example for adding graph to Anna's graph group <urn:Anna:Sponged:Data>:

```
-- An error will be raised because "Brad" has not enough rights on that group

reconnect "Brad";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Anna:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

   b. Example for adding graph to Brad's graph group <urn:Brad:Sponged:Data>:

```
-- No error will be raised as Brad has the efficient rights for graph group <urn:Brad:Spong

reconnect "Brad";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Brad:Sponged:Data>
  SELECT *
  FROM <http://example.com/brad/>
  WHERE
    { ?s ?p ?o };
```

   c. Example for adding graph to Carl's graph group <urn:Carl:Sponged:Data>:

```
-- An error will be raised because "Brad" has not enough rights on that group

reconnect "Brad";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

9. Examples check Carl's sponging permissions on different graph groups:

   a. Example for adding graph to Anna's graph group <urn:Anna:Sponged:Data>:

```
-- An error will be raised because "Carl" has not enough rights on that group

reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Anna:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

   b. Example for adding graph to Brad's graph group <urn:Brad:Sponged:Data>:

```
-- An error will be rased because "Carl" has not enough rights on that group

reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
```

```
  DEFINE get:private <urn:Brad:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

c. Example for adding graph to Carl's graph group <urn:Carl:Sponged:Data>:

```
-- No error will be raised as Carl has the efficient rights for graph group <urn:Brad:Spong

reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://example.com/carl/>
  WHERE
    { ?s ?p ?o };
```

10. User Carl performs private sponging:

```
reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://www.openlinksw.com/data/turtle/products.ttl>
  WHERE
    { ?s ?p ?o };

-- Should return for ex. 365 rows.
SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT COUNT(*)
  FROM <http://www.openlinksw.com/data/turtle/products.ttl>
  WHERE
    { ?s ?p ?o };

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM NAMED <http://www.openlinksw.com/data/turtle/software.ttl>
  FROM NAMED <http://www.openlinksw.com/data/turtle/licenses.ttl>
  WHERE
    {
      graph ?g
        { ?s ?p ?o
      }
    };

-- Should return for ex. 1317 rows.
SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT COUNT(*)
  FROM NAMED <http://www.openlinksw.com/data/turtle/software.ttl>
  FROM NAMED <http://www.openlinksw.com/data/turtle/licenses.ttl>
  WHERE
    {
      graph ?g
        { ?s ?p ?o
      }
    };
```

11. Viewing Graph Groups shows Carl's graph group <urn:Carl:Sponged:Data> contains total 4 graphs:

```
SQL> SELECT id_to_iri (RGGM_GROUP_IID), id_to_iri(RGGM_MEMBER_IID)
     FROM DB.DBA.RDF_GRAPH_GROUP_MEMBER
     ORDER BY 1,2;

id_to_iri                id_to_iri__1
```

```
VARCHAR                  VARCHAR
_________________________________________________________________

....
urn:Anna:Sponged:Data    http://example.com/anna/
urn:Brad:Sponged:Data    http://example.com/brad/
urn:Carl:Sponged:Data    http://example.com/carl/
urn:Carl:Sponged:Data    http://www.openlinksw.com/data/turtle/licenses.ttl
urn:Carl:Sponged:Data    http://www.openlinksw.com/data/turtle/products.ttl
urn:Carl:Sponged:Data    http://www.openlinksw.com/data/turtle/software.ttl
```

Example Performing Sponging with Private Graphs Using get:private pragma

The following example demonstrates how private sponging using get:private pragma works for database with private graphs.

1. Create few users in alphabetical order:

```
DB.DBA.USER_CREATE ('Anna', 'Anna');
DB.DBA.USER_CREATE ('Brad', 'Brad');
DB.DBA.USER_CREATE ('Carl', 'Carl');
```

2. Set to Anna, Brad and Carl SPARQL SELECT, UPDATE and SPONGE permissions:

```
grant SPARQL_SELECT to "Anna";
grant SPARQL_SELECT to "Brad";
grant SPARQL_SELECT to "Carl";

grant SPARQL_UPDATE to "Anna";
grant SPARQL_UPDATE to "Brad";
grant SPARQL_UPDATE to "Carl";

grant SPARQL_SPONGE to "Anna";
grant SPARQL_SPONGE to "Brad";
grant SPARQL_SPONGE to "Carl";
```

3. Set specific privileges: Setup assuming 3 users: Anna, Brad and Carl where each of these individual users has read access to graphs:

```
-- Close any public access to "private" graphs
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('nobody', 0, 1);

-- Set Read Only for public on graphs not listed as "private".
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('nobody', 1);

DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Anna', 0, 1);
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Brad', 0, 1);
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Carl', 0, 1);

DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Anna', 1);
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Brad', 1);
DB.DBA.RDF_DEFAULT_USER_PERMS_SET ('Carl', 1);
```

4. Assuming the following four sorts of access that are specified by four bits of an integer "permission bit-mask", following plain old UNIX style:

    - Bit 1 permits read access.
    - Bit 2 permits write access via SPARUL and is basically useless without bit 1 set.
    - Bit 4 permits write access via "RDF Network Resource Fetch" methods and is basically useless without bits 1 and 2 set.
    - Bit 8 allows retrieval of the list of members of a graph group. An IRI can be used as a graph IRI and as a graph group IRI at the same time, so bit 8 can be freely combined with any of bits 1, 2 or 4.
    - In the statements from below should be considered:

        - "15 = 8+4+2+1" -- i.e. combining all the four sorts of access FROM above
        - "9 = 8 + 1" -- i.e. read access + access to retrieve the list of members for a given graph group

```
-- Create Graph Group for Anna and set privileges:
DB.DBA.RDF_GRAPH_GROUP_CREATE ('urn:Anna:Sponged:Data', 1);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Anna:Sponged:Data', 'Anna', 15);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Anna:Sponged:Data', 'Brad', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Anna:Sponged:Data', 'Carl', 9);
```

```
-- Create Graph Group for Brad and set privileges:
DB.DBA.RDF_GRAPH_GROUP_CREATE ('urn:Brad:Sponged:Data', 1);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Brad:Sponged:Data', 'Anna', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Brad:Sponged:Data', 'Brad', 15);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Brad:Sponged:Data', 'Carl', 9);

-- Create Graph Group for Carl and set privileges:
DB.DBA.RDF_GRAPH_GROUP_CREATE ('urn:Carl:Sponged:Data', 1);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Carl:Sponged:Data', 'Anna', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Carl:Sponged:Data', 'Brad', 9);
DB.DBA.RDF_GRAPH_USER_PERMS_SET ('urn:Carl:Sponged:Data', 'Carl', 15);

-- Set Anna's, Brad's and Carl's graphs by inserting them into the <b>virtrdf:PrivateGraphs</b> gr
DB.DBA.RDF_GRAPH_GROUP_INS ('http://www.openlinksw.com/schemas/virtrdf#PrivateGraphs', 'http://exa
DB.DBA.RDF_GRAPH_GROUP_INS ('http://www.openlinksw.com/schemas/virtrdf#PrivateGraphs', 'http://exa
DB.DBA.RDF_GRAPH_GROUP_INS ('http://www.openlinksw.com/schemas/virtrdf#PrivateGraphs', 'http://exa
```

5. Examples with invalid graph group names:

   a. Example with Non-existing Graph Group:

```
-- An error for non-existing Graph group <http://nosuch/> will be raised.

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <http://nosuch/>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

   b. Example with "virtrdf:PrivateGraphs" graph group which is reserved for system usage:

```
-- An error for attempt to add a graph to special
-- graph group <http://www.openlinksw.com/schemas/virtrdf#PrivateGraphs> will be raised.

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private virtrdf:PrivateGraphs
  SELECT * FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

   c. Example with "virtrdf:rdf_repl_graph_group" graph group which is reserved for system usage:

```
-- An error for attempt to add a graph to special
-- graph group <http://www.openlinksw.com/schemas/virtrdf#rdf_repl_graph_group> will be rai

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private virtrdf:rdf_repl_graph_group
  SELECT * FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

6. Examples to check Anna's sponging permissions on different graph groups:

   a. Example for adding graph to Anna's graph group <urn:Anna:Sponged:Data>:

```
-- No error will be raised as Anna has the efficient rights for graph group <urn:Anna:Spong

reconnect "Anna";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Anna:Sponged:Data>
  SELECT *
  FROM <http://example.com/anna/>
  WHERE
    { ?s ?p ?o };
```

   b. Example for adding graph to Brad's graph group <urn:Brad:Sponged:Data>:

```
-- An error will be raised because "Anna" has not enough rights on that group

reconnect "Anna";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Brad:Sponged:Data>
  SELECT * FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

c. Example for adding graph to Carl's graph group <urn:Carl:Sponged:Data>:

```
-- An error will be raised because "Anna" has not enough rights on that group

reconnect "Anna";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

7. Examples check Brad's sponging permissions on different graph groups:

a. Example for adding graph to Anna's graph group <urn:Anna:Sponged:Data>:

```
-- An error will be raised because "Brad" has not enough rights on that group

reconnect "Brad";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Anna:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

b. Example for adding graph to Brad's graph group <urn:Brad:Sponged:Data>:

```
-- No error will be raised as Brad has the efficient rights for graph group <urn:Brad:Spong

reconnect "Brad";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Brad:Sponged:Data>
  SELECT *
  FROM <http://example.com/brad/>
  WHERE
    { ?s ?p ?o };
```

c. Example for adding graph to Carl's graph group <urn:Carl:Sponged:Data>:

```
-- An error will be raised because "Brad" has not enough rights on that group

reconnect "Brad";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

8. Examples check Carl's sponging permissions on different graph groups:

a. Example for adding graph to Anna's graph group <urn:Anna:Sponged:Data>:

```
-- An error will be raised because "Carl" has not enough rights on that group
```

```
reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Anna:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

b. Example for adding graph to Brad's graph group <urn:Brad:Sponged:Data>:

```
-- An error will be rased because "Carl" has not enough rights on that group

reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Brad:Sponged:Data>
  SELECT *
  FROM <http://example.com/>
  WHERE
    { ?s ?p ?o };
```

c. Example for adding graph to Carl's graph group <urn:Carl:Sponged:Data>:

```
-- No error will be raised as Carl has the efficient rights for graph group <urn:Brad:Spong

reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://example.com/carl/>
  WHERE
    { ?s ?p ?o };
```

9. User Carl performs private sponging:

```
reconnect "Carl";

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM <http://www.openlinksw.com/data/turtle/products.ttl>
  WHERE
    { ?s ?p ?o };

-- Should return for ex. 365 rows.
SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT COUNT(*)
  FROM <http://www.openlinksw.com/data/turtle/products.ttl>
  WHERE
    { ?s ?p ?o };

SPARQL
  DEFINE get:soft "replacing"
  DEFINE get:private <urn:Carl:Sponged:Data>
  SELECT *
  FROM NAMED <http://www.openlinksw.com/data/turtle/software.ttl>
  FROM NAMED <http://www.openlinksw.com/data/turtle/licenses.ttl>
  WHERE
    {
      graph ?g
        { ?s ?p ?o
      }
    };

-- Should return for ex. 1317 rows.
SPARQL
  DEFINE get:soft "replacing"
```

```
DEFINE get:private <urn:Carl:Sponged:Data>
SELECT COUNT(*)
FROM NAMED <http://www.openlinksw.com/data/turtle/software.ttl>
FROM NAMED <http://www.openlinksw.com/data/turtle/licenses.ttl>
WHERE
  {
    graph ?g
      { ?s ?p ?o
    }
  };
```

10. User Anna reads Carl's data:

```
SQL> reconnect "Anna";
SQL> SPARQL
  SELECT COUNT(*)
  FROM <http://www.openlinksw.com/data/turtle/products.ttl>
  WHERE
    { ?s ?p ?o };

callret-0

16.5. Linked Data Views over RDBMS Data Source

Linked Data Views map relational data into RDF and allow customizing RDF representation of locally stored RDF data. To let SPARQL clients access relational data as well as physical RDF graphs in a single query, we introduce a declarative Meta Schema Language for mapping SQL Data to RDF Ontologies. As a result, all types of clients can efficiently access all data stored on the server. The mapping functionality dynamically generates RDF Data Sets for popular ontologies such as SIOC, SKOS, FOAF, and ATOM/OWL without disruption to the existing database infrastructure of Web 1.0 or Web 2.0 solutions. Linked Data Views are also suitable for declaring custom representation for RDF triples, e.g. property tables, where one row holds many single-valued properties.

16.5.1. Introduction

The Virtuoso Linked Data Views meta schema is a built-in feature of Virtuoso's SPARQL to SQL translator. It recognizes triple patterns that refer to graphs for which an alternate representation is declared and translates these into SQL accordingly. The main purpose of this is evaluating SPARQL queries against existing relational databases. There exists previous work from many parties for rendering relational data as RDF and opening it to SPARQL access. We can mention D2RQ, SPASQL, Squirrel RDF, DBLP and others. The Virtuoso effort differs from these mainly in the following:

- Integration with a triple store. Virtuoso can process a query for which some triple patterns will go to local or remote relational data and some to local physical RDF triples.
- SPARQL query can be used in any place where SQL can. Database connectivity protocols are neutral to the syntax of queries they transmit, thus any SQL client, e.g. JDBC, ODBC or XMLA application, can send SPARQL queries and fetch result sets. Moreover, a SQL query may contain SPARQL subqueries and SPARQL expressions may use SQL built-in functions and stored procedures.
- Integration with SQL. Since SPARQL and SQL share the same run time and query optimizer, the query compilation decisions are always made with the best knowledge of the data and its location. This is especially important when mixing triples and relational data or when dealing with relational data distributed across many outside databases.
- No limits on SPARQL. It remains possible to make queries with unspecified graph or predicate against mapped relational data, even though these may sometimes be inefficient.
- Coverage of the whole relational model. Multi-part keys etc. are supported in all places.

16.5.2. Rationale

Since most of the data that is of likely use for the emerging semantic web is stored in relational databases, the argument for exposing this to SPARQL access is clear. We note that historically, SQL access to relational data has essentially never been given to the public outside of the organization. If programmatic access to corporate IS has been available to partners or the public, it has

been through dynamic web pages or more recently web services. There are reasons of performance, security, maintainability and so forth for this.

The culture of the emerging semantic web is however taking a different turn. Since RDF and OWL offer a mergeable and queryable model for heterogeneous data, it is more meaningful and maintainable to expose selected data for outside query than it would be with SQL. Advances in hardware make this also less of a performance issue than it would have been in the client-server database era.

In the context of Virtuoso, since Virtuoso is originally a virtual/federated database, incorporating SPARQL to relational mapping is an evident extension of the product's mission as a multi-protocol, multi-platform connector between information systems.

16.5.3. Quad Map Patterns, Values and IRI Classes

In the simplest sense, any relational schema can be rendered into RDF by converting all primary keys and foreign keys into IRI's, assigning a predicate IRI to each column, and an rdf:type predicate for each row linking it to a RDF class IRI corresponding to the table. Then a triple with the primary key IRI as subject, the column IRI as predicate and the column's value as object is considered to exist for each column that is neither part of a primary or foreign key.

Strictly equating a subject value to a row and each column to a predicate is often good but is too restrictive for the general case.

- Multiple triples with the same subject and predicate can exist.
- A single subject can get single-valued properties from multiple tables or in some cases stored procedures.
- An IRI value of a subject or other field of a triple can be composed from more than one SQL value, these values may reside in different columns, maybe in different joined tables.
- Some table rows should be excluded from mapping.

Thus in the most common case the RDF meta schema should consist of independent transformations; the domain of each transformation is a result-set of some SQL *SELECT* statement and range is a set of triples. The *SELECT* that produce the domain is quite simple: it does not use aggregate functions, joins and sorting, only inner joins and *WHERE* conditions. There is no need to support outer joins in the RDF meta schema because NULLs are usually bad inputs for functions that produce IRIs. In the rare cases when NULLs are OK for functions, outer joins can be encapsulated in SQL views. The range of mapping can be described by a SPARQL triple pattern: a pattern field is a variable if it depends on table columns, otherwise it is a constant. Values of variables in the pattern may have additional restrictions on datatypes, when datatypes of columns are known.

This common case of an RDF meta schema is implemented in Virtuoso, with one adjustment. Virtuoso stores quads, not triples, using the graph field (G) to indicate that a triple belongs to some particular application or resource. A SPARQL query may use quads from different graphs without large difference between G and the other three fields of a quad. E.g., variable *?g* in expression *GRAPH ?g {...}* can be unbound. SPARQL has special syntax for "graph group patterns" that is convenient for sets of triple patterns with a common graph, but it also has shorthands for common subject and predicate, so the difference is no more than in syntax. There is only one feature that is specific for graphs but not for other fields: the SPARQL compiler can create restrictions on graphs according to *FROM* and *FROM NAMED* clauses.

Virtuoso Linked Data Views should offer the same flexibility with the graphs as SPARQL addressing physical triples. A transformation cannot always be identified by the graph used for ranges because graph may be composed from SQL data. The key element of the meta schema is a "*quad map pattern* ". A simple quad map pattern fully defines one particular transformation from one set of relational columns into triples that match one SPARQL graph pattern. The main part of quad map pattern is four declarations of "*quad map values* ", each declaration specifies how to calculate the value of the corresponding triple field from the SQL data. The pattern also lists boolean SQL expressions that should be used to filter out unwanted rows of source data (and to join multiple tables if source columns belong to different tables). There are also quad map patterns that group together similar quad patterns but do not specify any real transformation or even prevent unwanted transformations from being used, they are described in "Grouping Map Patterns" below.

Quad map values refer to schema elements of two further types: "IRI classes" and "literal classes".

Note

In SQL, adding a new view can not break anything. This is because SQL lacks the ability of querying "everything" so data sources are always specified. This is not true for SPARQL, so please treat *any* metadata manipulation as potentially destructive operation. If an RDF storage is supposed to be used by more than one application then these applications should be tested together, not one after other, and they should be installed/upgraded on live database in the very same order as they were installed/upgraded on instrumental machine during testing. Always remember that these applications share RDF tables

Note

so they may interfere.

IRI Classes

An IRI class declares that a column or set of columns gets converted into a IRI in a certain way. The conversion of this sort can be declared revertible (bijection) so an IRI can be parsed into original SQL values; this is useful when some equality of an IRI constant and a calculated IRI can be replaced with an equality of a parse result of a constant and an SQL column that is index criteria or simply faster. In addition, the SPARQL optimizer will eliminate redundant conversions if one IRI class is explicitly declared as a subclass of another. The most flexible declaration for conversion consists of specifying functions that assemble and disassemble from IRI into its constituent parts. This is overkill for typical conversions so it is possible to specify only one sprintf-style format string such that *sprintf()* SQL function will print an IRI using this format and *sprintf_inverse()* will be able to parse it back.

The use of *sprintf_inverse()* assumes that the format does not contain fragments like *'%s%s'* that make it impossible to separate parts of IRI from each other.

In the following, we shall map the Virtuoso users and user roles system tables into the SIOC ontology.

```
create iri class oplsioc:user_iri "http://myhost/sys/user?id=%d"
  (in uid integer not null) .
create iri class oplsioc:group_iri "http://myhost/sys/group?id=%d"
  (in gid integer not null) .
create iri class oplsioc:membership_iri
  "http://myhost/sys/membership?super=%d&sub=%d"
  (in super integer not null, in sub integer not null) .
create iri class oplsioc:dav_iri "http://myhost%s"
  (in path varchar) .
```

These IRI classes are used for mapping data from the *DB.DBA.SYS_USERS* and *DB.DBA.SYS_ROLE_GRANTS* system tables that are defined in Virtuoso as follows:

```
create table DB.DBA.SYS_USERS (
  U_ID                integer not null unique,
  U_NAME              char (128) not null primary key,
  U_IS_ROLE           integer default 0,
  U_FULL_NAME         char (128),
  U_E_MAIL            char (128) default &amp;quot;,
  U_ACCOUNT_DISABLED  integer default 1,
  U_DAV_ENABLE        integer default 0,
  U_SQL_ENABLE        integer default 1,
  U_HOME              varchar (128),
. . .
 );
```

Single record in *DB.DBA.SYS_USERS* corresponds to a plain user or a group (role). Users and roles are collectively named "grantees". Thus a role may be granted to another role or to a user account. A role grant may be direct (explicit) or assigned by recursion.

```
create table SYS_ROLE_GRANTS (
  GI_SUPER   integer,
  GI_SUB     integer,
  GI_DIRECT  integer default 1,
. . .
  primary key (GI_SUPER, GI_SUB, GI_DIRECT));
```

One IRI class usually corresponds to one ontology class, because similar things are usually called similarly. One may wish to use identifiers of ontology classes as identifiers of related IRI classes, to not remember double number of names, e.g. *create IRI class mybank:XpressXfer* for subjects that will have *rdf:type* property *mybank:XpressXfer* made by mapping. That is technically possible but proven to become inconvenient and misleading as application evolves. While RDF types tend to persist, IRI classes may change over time or same subject may get more than one name via more than one IRI class, say, for exports to different systems. It is found to be more convenient to compose names of IRI classes by adding some common prefixes or suffixes to RDF classes (or to table names), say, write *create IRI class mybank:XpressXfer_iri* .

Literal Classes

A "literal class" declares that a column or set of columns gets converted into a literal instead of an IRI. More precisely, the result of conversion can be *IRI_ID* so it represents an IRI, but in current version of Virtuoso this is supported only for some internal built-in literal classes, not for classes declared by the user. So for user-defined literal class the result of the conversion is an RDF literal even if it is a string representation of a valid IRI.

In any case, a literal class can be used only in quad map values of O fields, because Virtuoso does not support literal values as subjects.

A special case of literal class is the identity class that converts a value from *varchar* column into an untyped literal and value from column of any other SQL datatype into a typed literal with type from XMLSchema set, i.e. *xsd:integer* , *xsd:dateTime* and so on. Columns of types *ANY* and *IRI_ID* are not supported.

The SPARQL optimizer knows that RDF literal types are pairwise disjoint so literal classes that produce literals of different types are known to be pairwise disjoint. The optimizer will replace a join on two disjoint literal classes with an empty statement, to simplify the resulting query.

Simple Quad Map Patterns

The following declaration of quad map pattern is self-explanatory. The line for *object* uses identity literal class so there's no need to specify its name.

```
graph      <http://myhost/sys>
subject    oplsioc:user_iri (DB.DBA.SYS_USERS.U_ID)
predicate  foaf:email
object     DB.DBA.SYS_USERS.U_E_MAIL
```

The description language also supports SPARQL-style notation that contains less keywords and eliminates duplicate graphs, subjects and predicates. The following add two patterns with constant graph IRI <*http://myhost/sys*> and subjects are made from column *DB.DBA.SYS_USERS.U_ID* by *oplsioc:user_iri* .

```
graph <http://myhost/sys>
  {
    oplsioc:user_iri (DB.DBA.SYS_USERS.U_ID)
      a sioc:user ;
      oplsioc:name DB.DBA.SYS_USERS.U_FULL_NAME .
  }
```

Assigning Names To Quad Map Patterns

In real applications, quad map patterns should be named, for schema manipulation and keeping debug info readable. Thus it is much better to rewrite the previous example as

```
create virtrdf:SysUsers as graph <http://myhost/sys>
  {
    oplsioc:user_iri (DB.DBA.SYS_USERS.U_ID)
      a sioc:user
          as virtrdf:SysUserType-User;
      oplsioc:name DB.DBA.SYS_USERS.U_FULL_NAME
          as virtrdf:SysUsersFullName .
  }
```

Using these names, one may later write, say, *drop quad map virtrdf:SysUserType-User* .

One name, *virtrdf:DefaultQuadMap* is reserved. It is an internal quad map pattern used to access "native-form" quads from *DB.DBA.RDF_QUAD* :

```
create virtrdf:DefaultQuadMap as
graph rdfdf:default-iid-nonblank (DB.DBA.RDF_QUAD.G)
subject rdfdf:default-iid (DB.DBA.RDF_QUAD.S)
predicate rdfdf:default-iid-nonblank (DB.DBA.RDF_QUAD.P)
object rdfdf:default (DB.DBA.RDF_QUAD.O)
```

IRI classes from *rdfdf:...* namespace are also reserved.

Grouping Map Patterns

The previous example actually contains three map patterns, not two. The name *virtrdf:SysUsers* refers to a "*group map pattern* " that does not define any real transformation of relational data into RDF but helps organize quad map patterns into a tree. Group may contain both quad map patterns and other groups. A group can be manipulated as a whole, e.g. *drop quad map virtrdf:SysUsers* will remove all three map patterns.

16.5.4. Configuring RDF Storages

"*Quad Storage* " is a named set of quad map patterns. The declaration *define input:storage storage-name* states that a SPARQL query will be executed using only quad patterns of the given quad storage. Declarations of IRI classes, literal classes and quad patterns are shared between all quad storages of an RDF meta schema but every quad storage contains only a subset of all available quad patterns. Two quad storages are always defined:

- A

  virtrdf:default

  one usually consists of everything (all user-relational mappings plus

  virtrdf:DefaultQuadMap

  for "native-form" quads from

  DB.DBA.RDF_QUAD

)
- A

  virtrdf:empty

  storage refers solely to

  DB.DBA.RDF_QUAD

  and can not be altered.

Three statements for manipulating storages are

- *create quad storage storage-name { quad-map-decls } .*
- *alter quad storage storage-name { quad-map-decls-or-drops } .*
- *drop quad storage storage-name .*

A map pattern can be created only as a part of *create quad storage* or *alter quad storage* statement, so initially it is used by exactly one storage. It can be imported to some other storage using directive *create map-id using storage source-storage* . E.g., declarations of many storages create *virtrdf:DefaultQuadMap* using storage *virtrdf:DefaultQuadStorage* .

Only a "top-level" quad map pattern (standalone or a whole group with descendants) can be imported, member of a group can not. The import directive also can not be a part of some group declaration.

The directive *drop quad map map-name* removes a map from one storage when it appears inside *alter quad storage* statement. Otherwise it removes the map from all storages. There exists garbage collection for quad map patterns, so any unused map is immediately deleted. A group is deleted with all its descendants.

16.5.5. Translation Of SPARQL Triple Patterns To Quad Map Patterns

When a SPARQL query is compiled into SQL using a quad storage, every triple pattern should become a subquery that retrieves data from relational tables. This subquery is an *UNION ALL* of joins generated from appropriate quad map patterns. The complete SQL query is composed from these basic subqueries. Thus the first operation of the SQL generation for a triple pattern is searching for quad map patterns that may in principle produce triples that match the triple pattern.

The more restrictions contained in the triple pattern the fewer quad map patterns will be used. A triple pattern *graph ?g { ?s ?p ?o }* is common enough to invoke all data transformations of the storage. A triple pattern *graph <g> { ?s <p> <o> }* will usually intersect with the range of only one quad map. Sometimes it is possible to prove that the storage can not contain any data that matches the given triple pattern, hence zero number of members of *UNION ALL* will result in constantly empty result-set.

The search for quad maps for a given pair of triple pattern and quad map storage is quite simple. The storage is treated as a tree of map patterns where quad map patterns are leafs, grouping patterns are inner nodes and the whole storage is also treated as a grouping pattern that specify no fields and contains all top-level map patterns of the storage.

The tree is traversed from the root, left to right, non-leaf vertex are checked before their children. The check of a vertex consists of up to four field checks, for G, S, P and O. Every field check compares the field definition in the vertex and the corresponding field in the triple pattern, G and G, S and S and so on. Note that a non-leaf vertex defines less than four of its fields, e.g., the root vertex does not define any of its fields and top-level *graph map { ... }* defines only graph. Checks are performed only for defined fields and return one of three values: "failed", "passed", "full match", according to the following rules:

Table 16.8. Matching Triple Field and Vertex Field

Field of vertex	Field in triple pattern	Result
constant	same constant	full match
constant	different constant	failed
constant	variable of same type	passed
constant	variable of different type	failed
quad map value	constant of same type	full match
quad map value	constant of different type	failed
quad map value of type X	variable, X or subtype of X	full match
quad map value of type X	variable, supertype of X	passed
quad map value of type X	variable, type does not intersect with X	failed

If any of the checks fails, the vertex and all its children are excluded from the rest of processing. Otherwise, if all four fields are defined for the quad map pattern, the map is added to the list of matching map patterns. The difference between "passed" and "full match" is significant only if the map is declared with *option (exclusive)* If all performed checks return "full match" and *option (exclusive)* is set then the traverse of the tree is stopped as soon as all children of the vertex are traversed. The most typical use of this option is when the application developer is sure that all triples of a graph belong to his application and they come from his own quad map patterns, not from *DB.DBA.RDF_QUAD* . This is to prevent the SPARQL compiler from generating redundant subqueries accessing *DB.DBA.RDF_QUAD* . The declaration may look like

```
create quad storage <mystorage>
  {
    graph <mygraph> option (exclusive) { . . . }
    create virtrdf:DefaultQuadMap
      using storage virtrdf:DefaultQuadStorage .
  }
```

Exclusive patterns make the order of declarations important, because an exclusive declaration may "throw a shadow" on declarations after it. Consider a database that have a special table RDF_TYPE that caches all RDF types of all subjects in all graphs. Consider two declarations: all triples from graph <*http://myhost/sys*> and all triples with *rdf:type* predicate, both exclusive:

```
graph <http://myhost/sys> option (exclusive)
  {
    . . . # mapping of DB.DBA.SYS_USERS as in previous examples.
  }
graph rdfdf:default-iid-nonblank (DB.DBA.RDF_TYPE.G)
subject rdfdf:default-iid (DB.DBA.RDF_TYPE.S)
predicate rdf:type
object rdfdf:default (DB.DBA.RDF_TYPE.O)
option (exclusive)
```

The order of these declarations dictates that triple pattern

```
graph <http://myhost/sys> {?s rdf:type ?o}
```

is compiled using only quad map patterns of the graph declaration, ignoring second declaration (and of course ignoring default mapping rule, if any). An explicit *option (order N)* at the end of quad map pattern will tweak the priority. By default, order will grow from 1000 for the first declaration in the statement to 1999 for the last, explicit configuration is especially useful to make order persistent to *alter storage* statements.

The *option (exclusive)* trick is ugly, low-level and prone to cause compilation errors after altering storage declarations. When misused, it is as bad as "red cut" in PROLOG, but one must use this trick to build scalable storages.

The *option (exclusive)* helps the SPARQL compiler to prepare better SQL queries, but sometimes it is "too exclusive". For instance, if a grouping quad map pattern specify only quad map value for graph and no other fields then making it exclusive prohibits the use of all declarations of the storage after that one. Sometimes it is better to notify compiler that quads made by the given quad map pattern are supposed to be different from all quads made by declarations listed after the given one.

Consider an application that exports users' personal data as graphs whose IRIs looks like *http://www.example.com/DAV/home/* username*/RDF/personal/* ; the application makes a query and a triple pattern is proven to be restrictive enough to filter out all quads that are not similar to quads generated by the given quad map pattern (say, the graph is constant *http://www.example.com/DAV/home/JohnSmith/RDF/personal/*). The application do not hope to find any quads that match the pattern but made by other applications, because graphs named like in the pattern are supposed to be solely for this single purpose; if, say, DB.DBA.RDF_QUAD occasionally contains some quads with graph equal to *http://www.example.com/DAV/home/JohnSmith/RDF/personal/* then they can be ignored.

Under this circumstances, the quad map pattern may have *option (soft exclusive)* . That grants a permission to the compiler to ignore rest of storage as soon as it is proven that the triple pattern can not access quads that does not match the pattern. So if that is proven then the pattern is exclusive and it makes the query faster; when unsure, the compiler work like there is no option at all.

Note

The *option (exclusive)* can be used as a security measure, *option (soft exclusive)* can not. Say, if an financial application exports its data as a single graph *http://www.example.com/front-office/cash/* using *exclusive* then the query that explicitly refers to that graph will never access any quads written by the attacker into DB.DBA.RDF_QUAD using same graph IRI. The use of *soft exclusive* gives no such protection. From the compiler's perspective, the *option (soft exclusive)* is a hint that may be ignored, not an unambiguous order.

There is one exception from the rules described above. This exception is for *virtrdf:DefaultQuadStorage* only. If a graph variable of a quad map pattern is not bound and no source graph specified by *FROM* clauses then quad maps for specific constant graphs are ignored. In other words, if a default quad storage contains quad maps for specific graphs then the query in that storage should explicitly specify the graph in order to use a map for graph. This rule will not work if the default quad map is removed from the *virtrdf:DefaultQuadStorage* . This rule relates to the default storage itself, not to the containing patterns; copying some or all patterns into other storage will not reproduce there this special effect.

So for example the query from below returns results when graph is specified i.e. when no graph is referenced, then run over physical store only is performed:

```
SQL>SPARQL
SELECT *
WHERE
  {
    <http://localhost:8990/Demo/categories/CategoryID/1#this>  ?p ?o
  };
p         o
VARCHAR  VARCHAR
_______________________________________________________________________________

0 Rows. -- 0 msec.

16.5.6. Describing Source Relational Tables

Quad map patterns of an application usually share a common set of source tables and quad map values of one pattern usually share either a single table or very small number of joined tables. Join and filtering conditions are also usually repeated in different patterns. It is not necessary to type table descriptions multiple times, they are declare once in the beginning of storage declaration statement and shared between all quad map declarations inside the statement. Names of aliases can be used instead of table names in quad map values.

```
FROM DB.DBA.SYS_USERS as user WHERE (^{user.}^.U_IS_ROLE = 0)
FROM DB.DBA.SYS_USERS as group WHERE (^{group.}^.U_IS_ROLE = 1)
FROM DB.DBA.SYS_USERS as account
FROM user as active_user
  WHERE (^{active_user.}^.U_ACCOUNT_DISABLED = 0)
FROM DB.DBA.SYS_ROLE_GRANTS as grant
  WHERE (^{grant.}^.GI_SUPER = ^{account.}^.U_ID)
  WHERE (^{grant.}^.GI_SUB = ^{group.}^.U_ID)
  WHERE (^{grant.}^.GI_SUPER = ^{user.}^.U_ID)
```

This declares five distinct aliases for two distinct tables, and six filtering conditions. Every condition is an SQL expression with placeholders where a reference to the table should be printed. The SPARQL compiler will not try to parse texts of these expressions (except dummy search for placeholders), so any logical expressions are acceptable. When a quad map pattern declaration refers to some aliases, the *WHERE* clause of the generated SQL code will contain a conjunction of all distinct texts of "relevant" conditions. A condition is relevant if every alias inside the condition is used in some quad map value of the map pattern, either directly or via clause like *from user as active_user* . (*user* is a "*base alias* " for *active_user*).

Consider a group of four declarations.

```
graph <http://myhost/sys>
  {
    oplsioc:user_iri (active_user.U_ID)
        a oplsioc:active-user .
    oplsioc:membership_iri (grant.GI_SUPER, grant.GI_SUB).
        oplsioc:is_direct
            grant.GI_DIRECT ;
        oplsioc:member-e-mail
            active_user.U_E_MAIL
               where (^{active_user.}^.U_E_MAIL like 'mailto:%').
    ldap:account-ref (account.U_NAME)
        ldap:belongs-to
            ldap:account-ref (group.U_NAME) option (using grant).
  }
```

The first declaration will extend <*http://myhost/sys*> graph with one imaginary triples *{ user a oplsioc:active-user }* for every account record that is not a role and not disabled. The second declaration deals with membership records. A membership is a pair of a grantee ("super") and a granted role ("sub") stored as a row in *DB.DBA.SYS_ROLE_GRANTS*).

The second declaration states that every membership has *oplsioc:is_direct* property with value from *GI_DIRECT* column of that table (roles may be granted to other roles and users, so permissions are "direct" or "recursive").

The third declaration declares *oplsioc:member-e-mail* property of memberships. The value is a literal string from *DB.DBA.SYS_USERS.U_E_MAIL* , if the grantee is active (not disabled) and is not a role and its e-mail address starts with *'mailto:'* . The join between *DB.DBA.SYS_ROLE_GRANTS* and *DB.DBA.SYS_USERS* is made by equality *(GI_SUPER = U_ID)* because the alias *active_user* in the declaration "inherits" all conditions specified for *user* . In addition, the SPARQL compiler will add one more condition to check if the *U_E_MAIL* is not null because the NULL value is not a valid object and it knows that *U_E_MAIL* is not declared as *NOT NULL* .

The last declaration contains an *option* clause. As usual, this indicates that the basic functionality is good for many tasks but not for all. In this declaration, the *ldap:belongs-to* property establishes a relation between grantee (subject) and a granted role (object). Both subject and object IRIs are based on account name, *DB.DBA.SYS_USERS.U_NAME* , so the quad map pattern contains two references to different aliases of *DB.DBA.SYS_USERS* but no alias for *DB.DBA.SYS_ROLE_GRANTS* . Hence the declaration could produce a triple for every row of the Cartesian product of the *DB.DBA.SYS_USERS* . To fix the problem, *option (using alias-name)* tells the compiler to process the alias-name as if it's used in some quad map value of the pattern.

It is an error to use an alias only in *where* clause of the quad map pattern but neither in values or in *option (using alias-name)* . To detect more typos, an alias used in quad map values can not appear in *option (using alias-name)* clause.

16.5.7. Function-Based IRI Classes

Most of IRI classes can be declared by a sprintf format string, but sophisticated cases may require calculations, not only printing the string. *create IRI class using function* allows the application transform relational values to IRIs by any custom routines.

Let us extend the previous example about users and groups by a new class for grantees. Both users and groups are grantees and we have defined two IRI classes for them. Classes *oplsioc:user_iri* and *oplsioc:group_iri* work fine for quad maps of *U_ID* if and only if the value of *U_IS_ROLE* is accordingly restricted to FALSE or TRUE, otherwise one may occasionally generate, say, user IRI for a group. To create and parse IRIs that correspond to any U_IDs, two functions should be created:

```
create function DB.DBA.GRANTEE_URI (in id integer)
returns varchar
{
  declare isrole integer;
  isrole := coalesce ((SELECT top 1 U_IS_ROLE
      FROM DB.DBA.SYS_USERS WHERE U_ID = id ) );
  if (isrole is null)
    return NULL;
  else if (isrole)
    return sprintf ('http://%s/sys/group?id=%d', id);
  else
    return sprintf ('http://%s/sys/user?id=%d', id);
};

create function DB.DBA.GRANTEE_URI_INVERSE (in id_iri varchar)
returns integer
{
  declare parts any;
  parts := sprintf_inverse (id_iri,
      'http://myhost/sys/user?id=%d', 1 );
  if (parts is not null)
    {
      if (exists (SELECT top 1 1 FROM DB.DBA.SYS_USERS
          WHERE U_ID = parts[0] and not U_IS_ROLE ) )
        return parts[0];
    }
  parts := sprintf_inverse (id_iri,
      'http://myhost/sys/group?id=%d', 1 );
  if (parts is not null)
    {
      if (exists (SELECT top 1 1 FROM DB.DBA.SYS_USERS
          WHERE U_ID = parts[0] and U_IS_ROLE ) )
        return parts[0];
    }
  return NULL;
};
```

These functions may be more useful if the SPARQL web service endpoint is allowed to use them:

```
grant execute on DB.DBA.GRANTEE_URI to "SPARQL";
grant execute on DB.DBA.GRANTEE_URI_INVERSE to "SPARQL";
```

The next declaration creates an IRI class based on these two functions:

```
create iri class oplsioc:grantee_iri using
  function DB.DBA.GRANTEE_URI (in id integer)
    returns varchar,
  function DB.DBA.GRANTEE_URI_INVERSE (in id_iri varchar)
```

```
returns integer .
```

In common case, IRI class declaration contains an N-array function that composes IRIs and N inverse functions that gets an IRI as an argument and extracts the Nth SQL value. IRI composing function should silently return NULL on incorrect arguments instead of error signal. Inverse functions should return NULL if the argument has an incorrect type or value.

It is possible to specify only composing function without any of inverse functions. However *option (bijection)* can not be used in that case, obviously.

16.5.8. Connection Variables in IRI Classes

Writing function-based IRI class is overkill when the IRI can in principle be made by a `sprintf_iri` but the format should contain some context-specific data, such as host name used for the dynamic renaming of local IRIs . Format strings offer a special syntax for that cases. *%{varname}U* acts as *%U* but the function `sprintf` will take the value from client connection variable *varname* , not from list of arguments. Similarly, `sprintf_inverse` will not return fragment that match to *%{varname}U* in the vector of other fragments; instead it will get the value from connection environment and ensure that it matches the fragment of input; mismatch between printed and actual value of variable will means that the whole string do not match the format.

SPARQL optimizer knows about this formatting feature and sometimes it makes more deductions from occurrence of *%{varname}U* than from occurrence of plain *%U* , so this notation may be used in *option (returns ...)* when appropriate. Of course, the optimizer has no access to the actual value of connection variable because it may vary from run to run or may change between the compilation and the run, but the value is supposed to be persistent during any single query run so *%{myvariable}U* in one place is equal to *%{myvariable}U* in other.

Connection variables are set by `connection_set` and some of them have default values that are used if not overridden by application:

- *URIQADefaultHost*

  is for default host as it is specified in Virtuoso configuration file. Note, however, that it will be escaped when printed so if it contains colon and port number then the colon is escaped. In addition, there are special variables that match dynamic renaming of local IRIs more accurately.
- *WSHost*

  is for host and port as it is used by current client connection for dynamic renaming. The colon before port will be escaped.
- *WSHostName*

  is for host name only, without port, as it is used by current client connection for dynamic renaming.
- *WSHostPort*

  is for port part of host IRI. That is string, not integer. The only real use of the variable is in formats like

  http://%{WSHostName}U:%{WSHostPort}U/...

  .

It is inconvenient to write different format strings for different cases. Two most common policies are different host names for default HTTP port of a publicly available service and different non-default ports for one or more host names of an intranet installation; these two approaches are almost never used in a mix. So declaration of IRI classes may use shorthand *^{DynamicLocalFormat}^* in format strings that is expanded either to *http://%{WSHost}U* or to *http://%{WSHostName}U:%{WSHostPort}U/...* , depending on absence or presence of port number in the value of *DefaultHost* parameter of *URIQA* section of configuration file.

Note

*^{DynamicLocalFormat}^* is for IRI class declarations only and is not expanded in any other place, so it is useful sometimes to create an IRI class with empty argument list in order to get "almost constant" IRIs calculated without writing special procedures.

16.5.9. Lookup Optimization -- BIJECTION and RETURNS Options

There is one subtle problem with IRI class declarations. To get benefit from a relational index, SPARQL optimizer should compose equality between table column and some known SQL value, not between return value of IRI class and a known composed IRI. In addition, redundant calculations of IRIs takes time. To enable this optimization, an IRI class declaration should end with *option (bijection)* clause. For some simple format strings the compiler may recognize the bijection automatically but an explicit declaration is always a good idea.

Note:

See also: Wikipedia - Bijection . In mathematics, a bijection, or a bijective function is a function f from a set X to a set Y such that, for every y in Y, there is exactly one x in X such that f(x) = y.

Alternatively, f is bijective if it is a one-to-one correspondence between those sets; i.e., both one-to-one (injective) and onto (surjective).

The SPARQL compiler may produce big amounts of SQL code when the query contains equality of two calculated IRIs and these IRIs may come from many different IRI classes. It is possible to provide hints that will let the compiler check if two IRI classes form disjoint sets of possible IRI values. The more disjoint sets are found the less possible combinations remain so the resulting SQL query will contain fewer unions of joins. The SPARQL compiler can prove some properties of sprintf format strings. E.g., it can prove that set of all strings printed by "http://example.com/item%d" and the set of strings printed by "http://example.com/item%d/" are disjoint. It can prove some more complicated statements about unions and intersections of sets of strings. The IRI or literal class declaration may contain *option (returns ...)* clause that will specify one or more sprintf patterns that cover the set of generated values. Consider a better version of IRI class declaration listed above:

```
create iri class oplsioc:grantee_iri using
  function DB.DBA.GRANTEE_URI (in id integer)
    returns varchar,
  function DB.DBA.GRANTEE_URI_INVERSE (in id_iri varchar)
    returns integer
  option ( bijection,
    returns "http://myhost/sys/group?id=%d"
    union   "http://myhost/sys/user?id=%d" ) .
```

It is very important to keep IRI classes easily distinguishable by the text of IRI string and easy to parse.

- Format

  %U

  is better than

  %s

  , especially in the middle of IRI, because the

  %U

  fragment can not contain characters like "/" or "="; one may prove that

  /%U/

  and

  /abra%d/cadabra/

  are disjoint but

  /%s/

  and

  /abra%d/cadabra/

are not disjoint.

- It is better when the variable part like

  %U

  or

  %d

  is placed between characters that may not occur in the

  %U

  or

  %d

  output, i.e.

  %U

  is placed between "/", "&" or "=" and

  %d

  is placed between non-digits;

  order_line_%d

  is better than

  order-line-%d

  because minus may be part of

  %d

  output.
- End-of-line is treated as a special character, so placing

  %U

  or

  %d

  between "/" and end of line is as good as placing it between two "/".

In some cases *option (returns ...)* can be used for IRI classes that are declared using sprintf format, but actual data have more specific format. Consider a literal class declaration that is used to output strings and the application knows that all these strings are ISBN numbers:

```
create literal class example:isbn_ref "%s" (in isbn varchar not null)
  option ( bijection, returns "%u-%u-%u-%u" union "%u-%u-%u-X" )
```

Sometimes interoperability restrictions will force you to violate these rules but please try to follow them as often as possible.

16.5.10. Join Optimization -- Declaring IRI Subclasses

Additional problem appears when the equality is between two IRIs of two different IRI classes. Even if both of them are bijections, the compiler does not know if these IRI classes behave identically on the intersection of their domains. To let the

optimizer know this fact, one IRI class can be explicitly declared as a subclass of another:

```
make oplsioc:user_iri subclass of oplsioc:grantee_iri .
make oplsioc:group_iri subclass of oplsioc:grantee_iri .
```

The SPARQL compiler can not check the validity of a subclass declaration. The developer should carefully test functions to ensure that transformations are really subclasses, as well as to ensure that functions of an IRI class declarations are really inverse to each other.

When declaring that a table's primary key is converted into a IRI according to one IRI class, one usually declares that all foreign keys referring to this class also get converted into an IRI as per this same class, or subclass of same class.

Subclasses can be declared for literal classes as well as for IRI classes, but this case is rare. The reason is that most of literals are made by identity literal classes that are disjoint to each other even if values may be equal in SQL sense, such as *"2"* of type *xsd:integer* and *"2.0"* of type *xsd:double* .

16.5.11. RDF Metadata Maintenance and Recovery

This section refers to checking and backing up Linked Data View and storage declarations only. The checks and backup/restore do not affect physical quads, relational schema or tables or data therein. For general backup and restore, see server administration. To detect and fix automatically most popular sorts of RDF metadata corruption use `DB.DBA.RDF_AUDIT_METADATA` . It is also possible to backup RDF data by `DB.DBA.RDF_BACKUP_METADATA` and restore the saved state later by using `DB.DBA.RDF_RESTORE_METADATA` . It is convenient to make a backup before any modification of quad storages, quad map patterns or IRI classes, especially during debugging new Linked Data Views.

Note

In SQL, adding a new view can not break anything. This is because SQL lacks the ability of querying "everything" so data sources are always specified. This is not true for SPARQL, so please treat *any* metadata manipulation as potentially destructive operation. If an RDF storage is supposed to be used by more than one application then these applications should be tested together, not one after other, and they should be installed/upgraded on live database in the very same order as they were installed/upgraded on instrumental machine during testing. Always remember that these applications share RDF tables so they may interfere.

16.5.12. Split Linked Data View

Linked Data View can be created by two or more "sparql alter storage" statements. In each statement can be created one quad map that contains mappings for half or a third of all tables. Quad maps created should have distinct names but may mention same graph. The important fact is that if the Linked Data View in question is exclusive for a graph then only the last quad map should be exclusive but all previous should not have this option. This is because if a map is exclusive on a graph the rest of maps on that graph will be silently ignored.

The example below shows a sample part of the Virtuoso eCRM Views code, where the Linked Data View is split in two parts: with quad map virtrdf:ecrmDemo1 and with quad map virtrdf:ecrmDemo2:

```

                            as virtrdf:Order-COMPANY_REL_ID .

...
            } .
} .
;
```

16.5.13. Linked Data Views and recursive FK relationships

Here is sample example of a script to include an additional table alias for a table:

```
alter quad storage virtrdf:DefaultQuadStorage
  :
  FROM isports_rdf.prs10_isports_rdf.VRef_Call      as Ref_Call_tbl
  FROM isports_rdf.prs10_isports_rdf.VRef_Call      as Ref_Call_tbl_1
  :
{
```

```
  :
  refcall:ref-call_iri (Ref_Call_tbl.Call_Num) a refcall:Ref-Call as
virtrdf:ref-call_pk ;
  :
  refcall:has_parent  refcall:ref-call_iri (Ref_Call_tbl_1.Call_Num)
where  ( ^{Ref_Call_tbl.}^.Parent    = ^{Ref_Call_tbl_1.}^.Call_Num )   as
virtrdf:Ref-Call_has_parent .
```

This demonstrates the way to self-join the table VRef_Call with itself. Like in SQL, are needed two different aliases for one table if you want to join it with itself.

16.6. Automated Generation of Linked Data Views over Relational Data Sources

16.6.1. Introduction

Virtuoso offers from Conductor UI an HTML based Wizard interface for dynamically generating & publishing RDF based Linked Data from ODBC or JDBC accessible relational data sources. Basically, a mechanism for building RDF based Linked Data views over relational data sources.

The proliferation of relational databases across enterprises and behind Web sites, makes them a vital data source for the burgeoning Linked Data Web. Thus, the process of publishing Linked Data from these sources needs to be as unobtrusive as possible. Naturally, a balance has to be struck between unobtrusive generation of Linked Data and traditional relational database management system (RDBMS) virtues such as:

- Scalability
- Security
- Analytical Expressivity of SQL
- Separation of Data Access and Data Storage via ODBC, JDBC, ADO.NET CLIs.

The following steps must be taken to publish RDF-based Linked Data:

1. Identifying ODBC or JDBC data sources that host the data you seek to publish (assuming the data isn't Virtuoso RDBMS hosted -- in which case, skip ahead to step #3).
2. Attach/Link TABLEs or VIEWs from the external data sources into Virtuoso via their Data Source Names (DSNs).
3. Identify the internal or external TABLEs or VIEWs that hold the data you wish to publish.
4. Configure Endpoints and Re-write Rules to disambiguate data object (resource) identity and description through HTTP-based content negotiation.
5. Expose the Data Source Ontology and associated Instance Data in Linked Data form through those Endpoints and Re-write Rules.

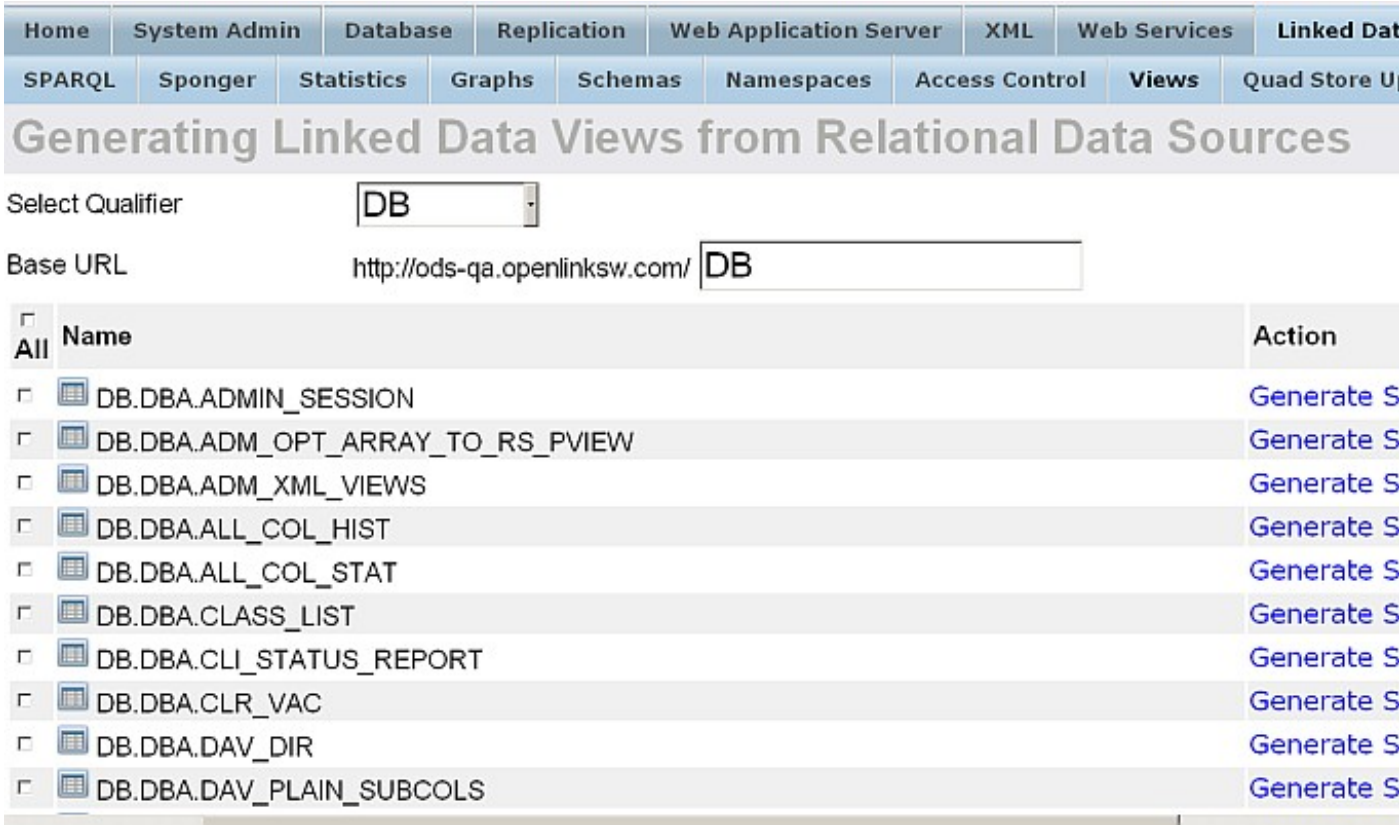
These steps may be largely automated (the "One-Click" Deployment below), or performed manually ("Using the Conductor's HTML-based Wizard" further down).

16.6.2. One Click Linked Data Generation & Deployment

The following steps provide a one-click guide for publishing ODBC- or JDBC-accessible RDBMS data in RDF Linked Data form, using the "Generate & Publish" Conductor feature.

1. Go to http://<cname>:port/conductor ;
2. Log in as user dba (or another user with DBA privileges);
3. Follow menu path Linked Data -> Views;

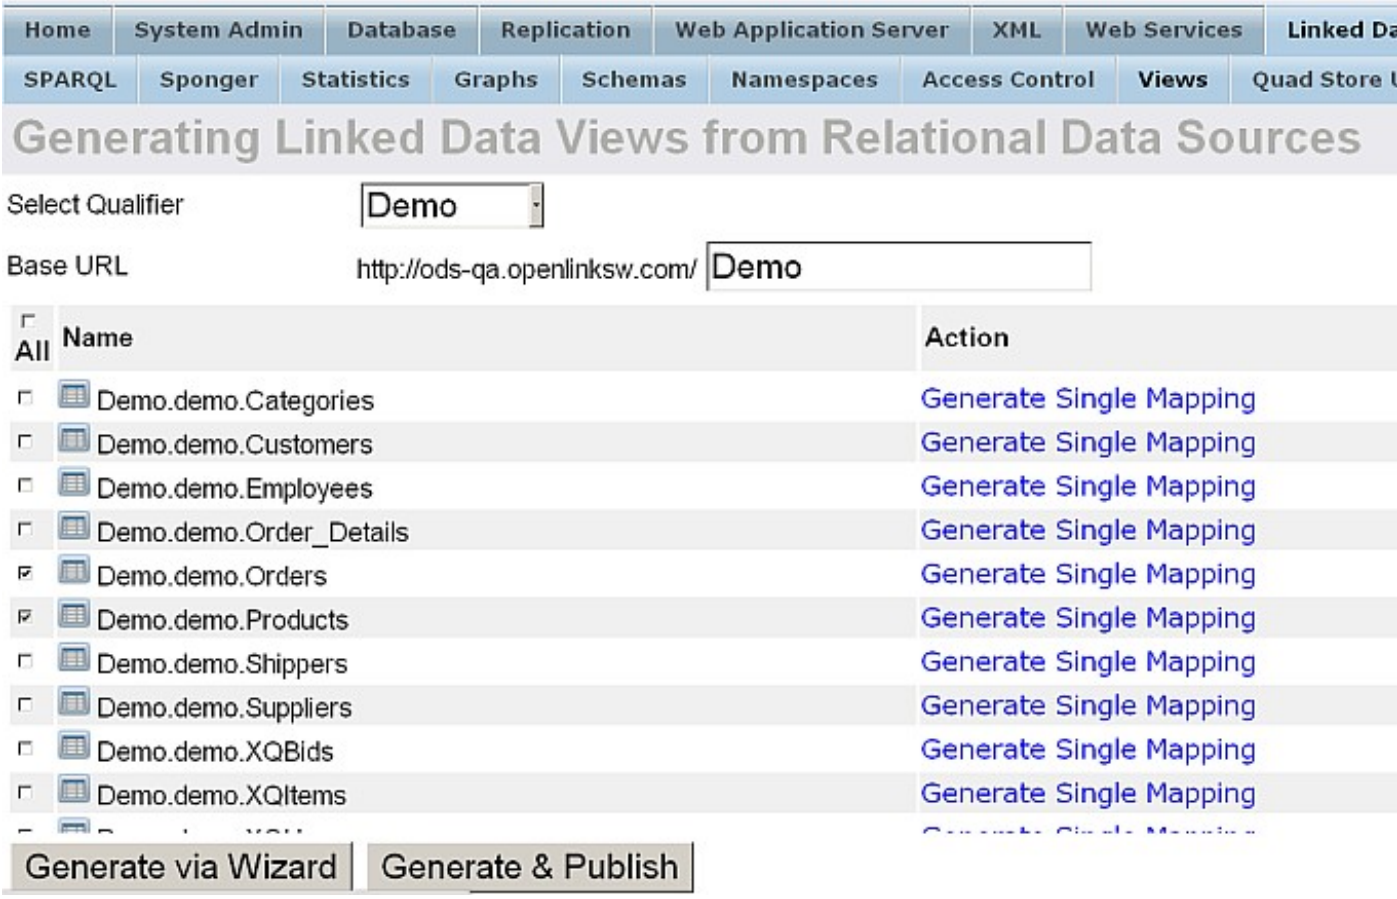
Figure 16.52. Linked Data Views



4. In the form presented, perform the following steps:

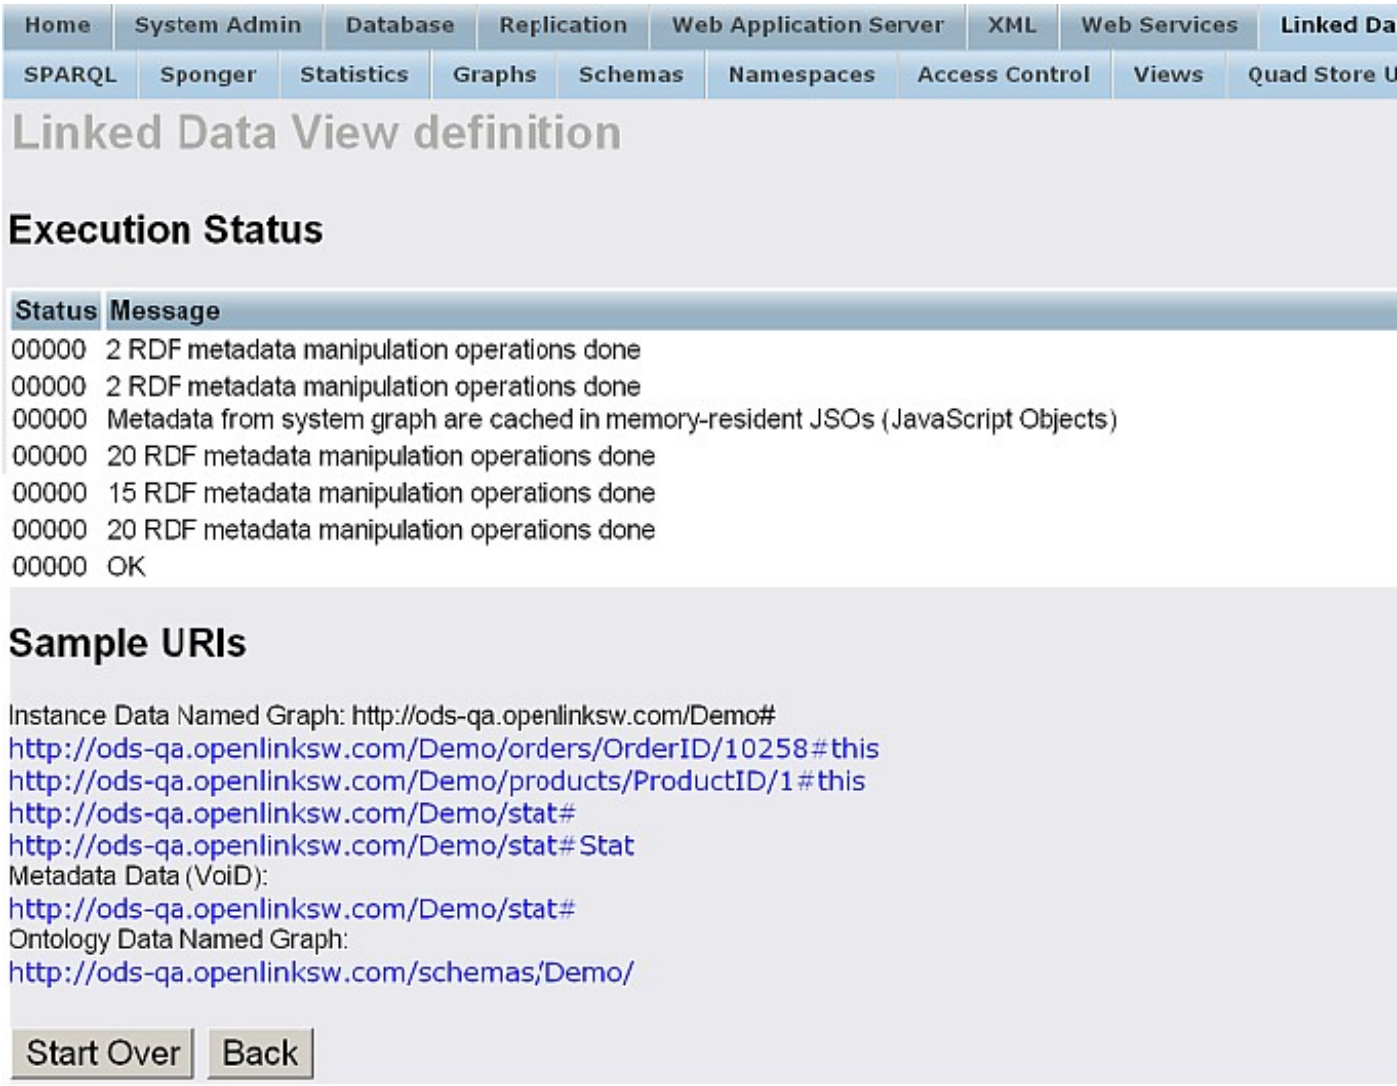
    a. Select the Database Name Qualifier (e.g., "Demo") that exposes the Tables / Views for this exercise
    b. Enter the Base URL to which your URL rewrite rules will be bound (e.g. http://<cname>:8890/Demo)
    c. Select specific Tables containing the data to be published (e.g. Demo.demo.Orders and Demo.demo.Products)
    d. Click the "Generate & Publish" button

Figure 16.53. Linked Data Views Generate and Publish



5. Virtuoso will perform the entire process of ontology generation, instance data generation, and linked data deployment (re-write rules generation and application).
6. Error messages will be presented if the Wizard encounters problems. If there are no error messages, your Linked Data View declarations and Linked Data publishing activities will have completed successfully.

Figure 16.54. Linked Data View declarations and Linked Data publishing activities



7. Optionally, you could also perform one of the following tasks:

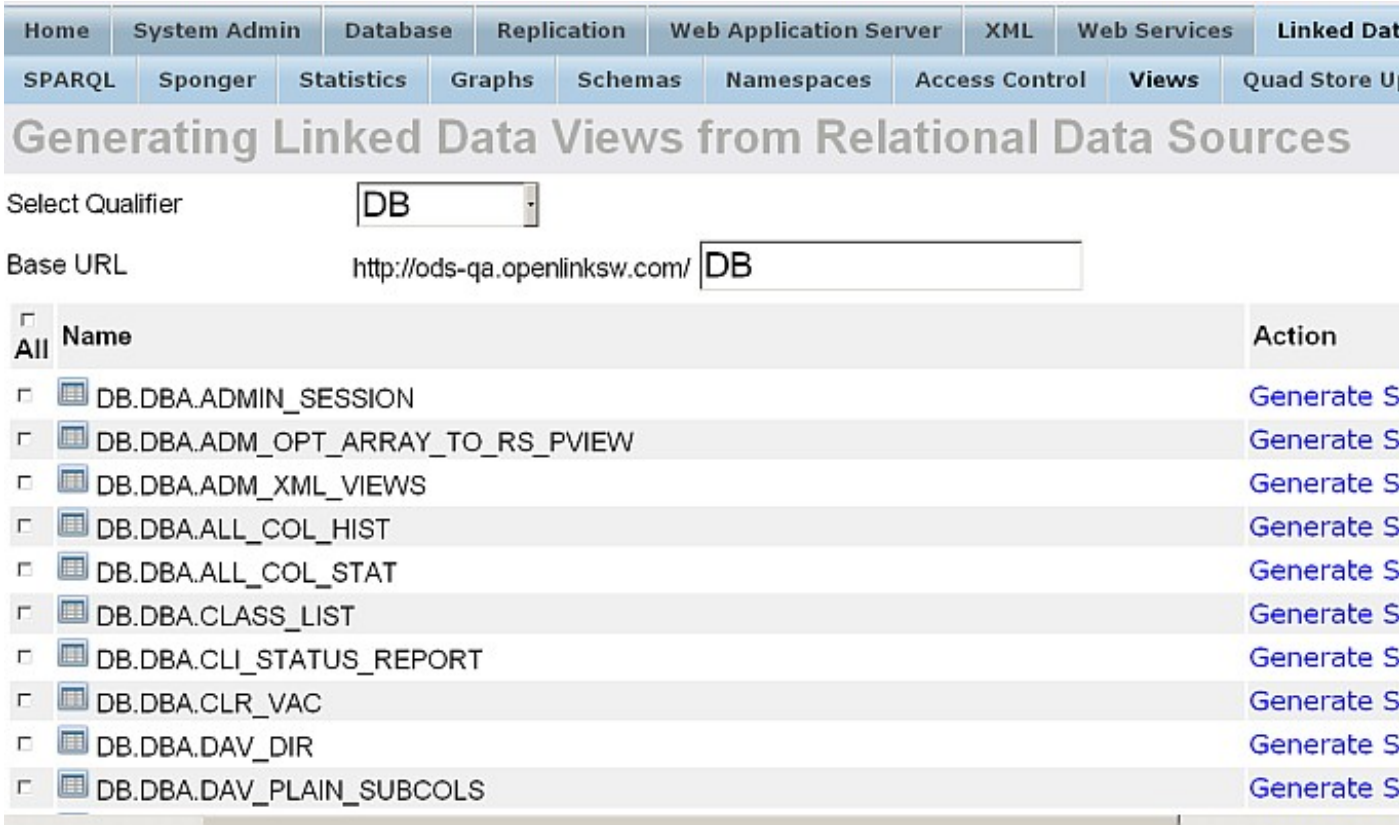
    a. Save Data Mappings: when clicked, offers to save the generated Definitions to local file system
    b. Save Ontology Mappings: when clicked, offers to save the generated Ontology to local file system
    c. Click on the "Cancel" should you want to return to the initial Linked Data View Generation form.

16.6.3. Manual Linked Data Generation & Deployment using the Conductor's HTML-based wizard

The following step-by guide will lead you through manually publishing ODBC- or JDBC-accessible RDBMS data in RDF Linked Data form, using the Conductor's HTML-based wizard:

1. Go to http://<cname>:port/conductor
2. Log in as user dba (or another user with DBA privileges)
3. Follow menu path Linked Data -> Views

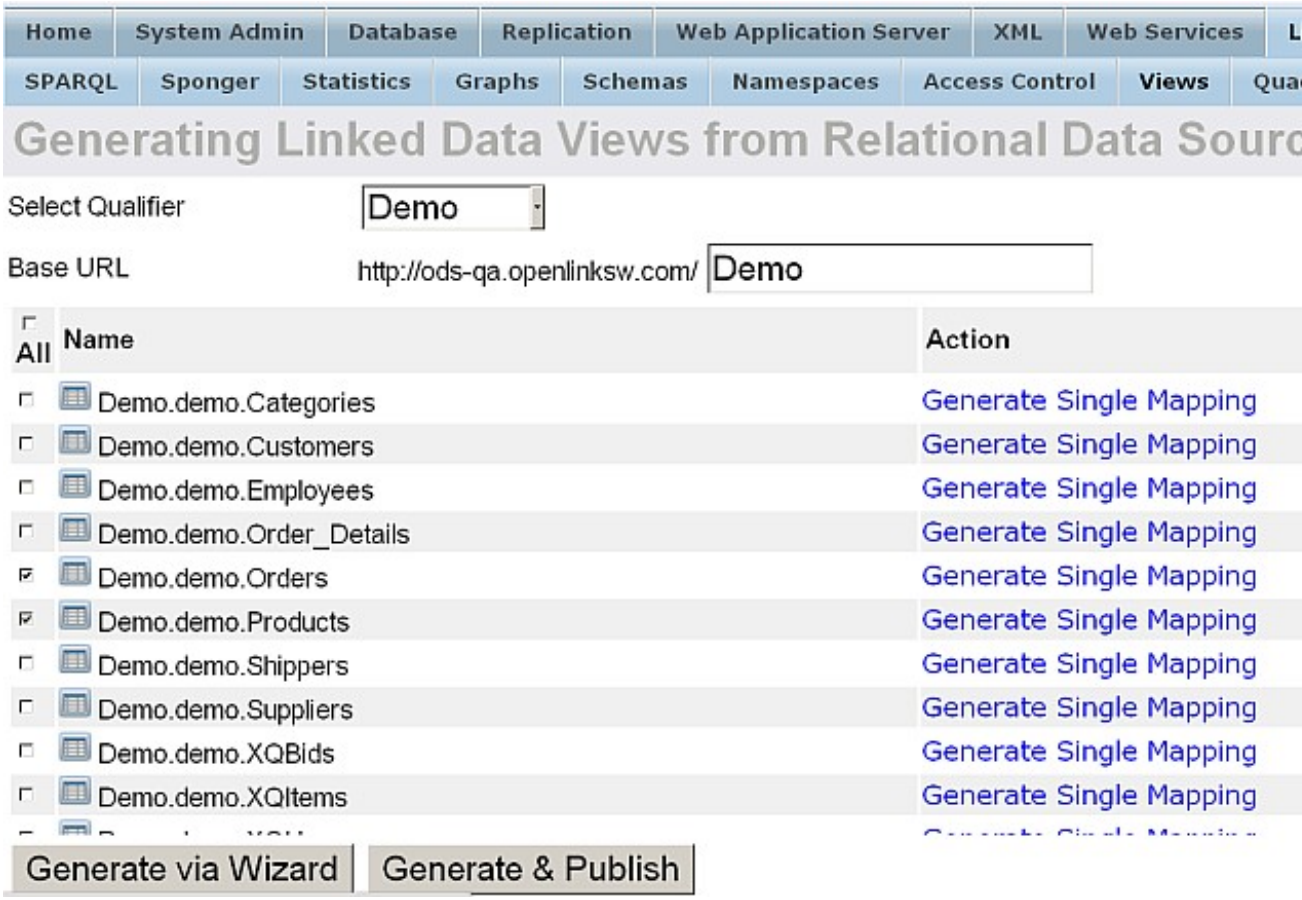
Figure 16.55. Linked Data Views



4. In the form presented, perform the following steps:

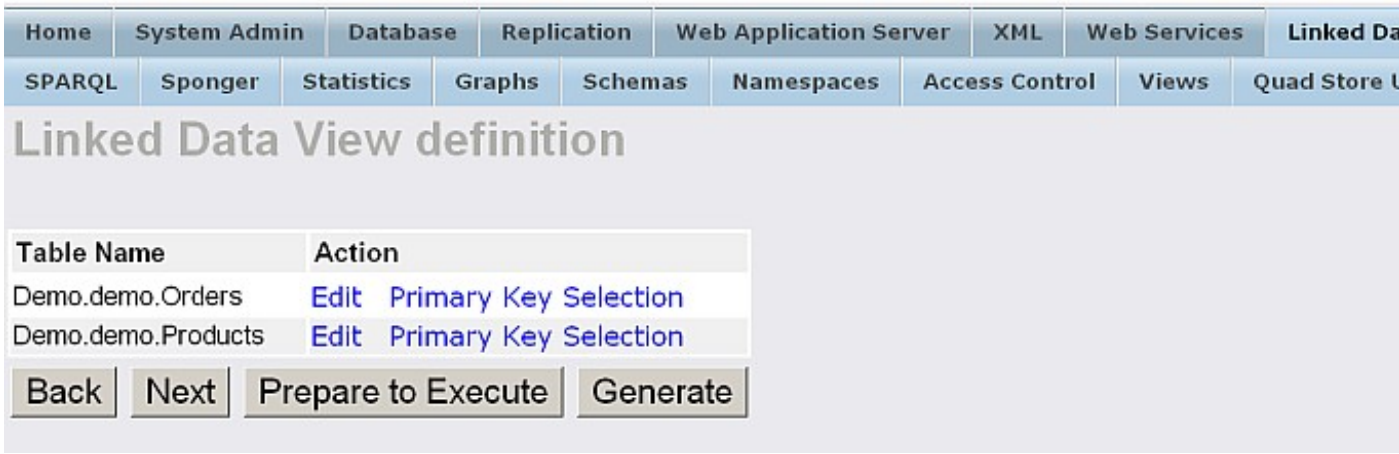
    a. Select the Database Name Qualifier (e.g., "Demo") that exposes the Tables / Views for this exercise
    b. Enter the Base URL to which your URL rewrite rules will be bound (e.g. http://<cname>:8890/Demo)
    c. Select specific Tables containing the data to be published (e.g., Demo.demo.Orders and Demo.demo.Products)
    d. Click the "Generate via Wizard" button

    Figure 16.56. Generate via Wizard



5. At this point, you are presented with the option to edit your column selection. Select the "Edit" link, for example, for table Demo.demo.Products.

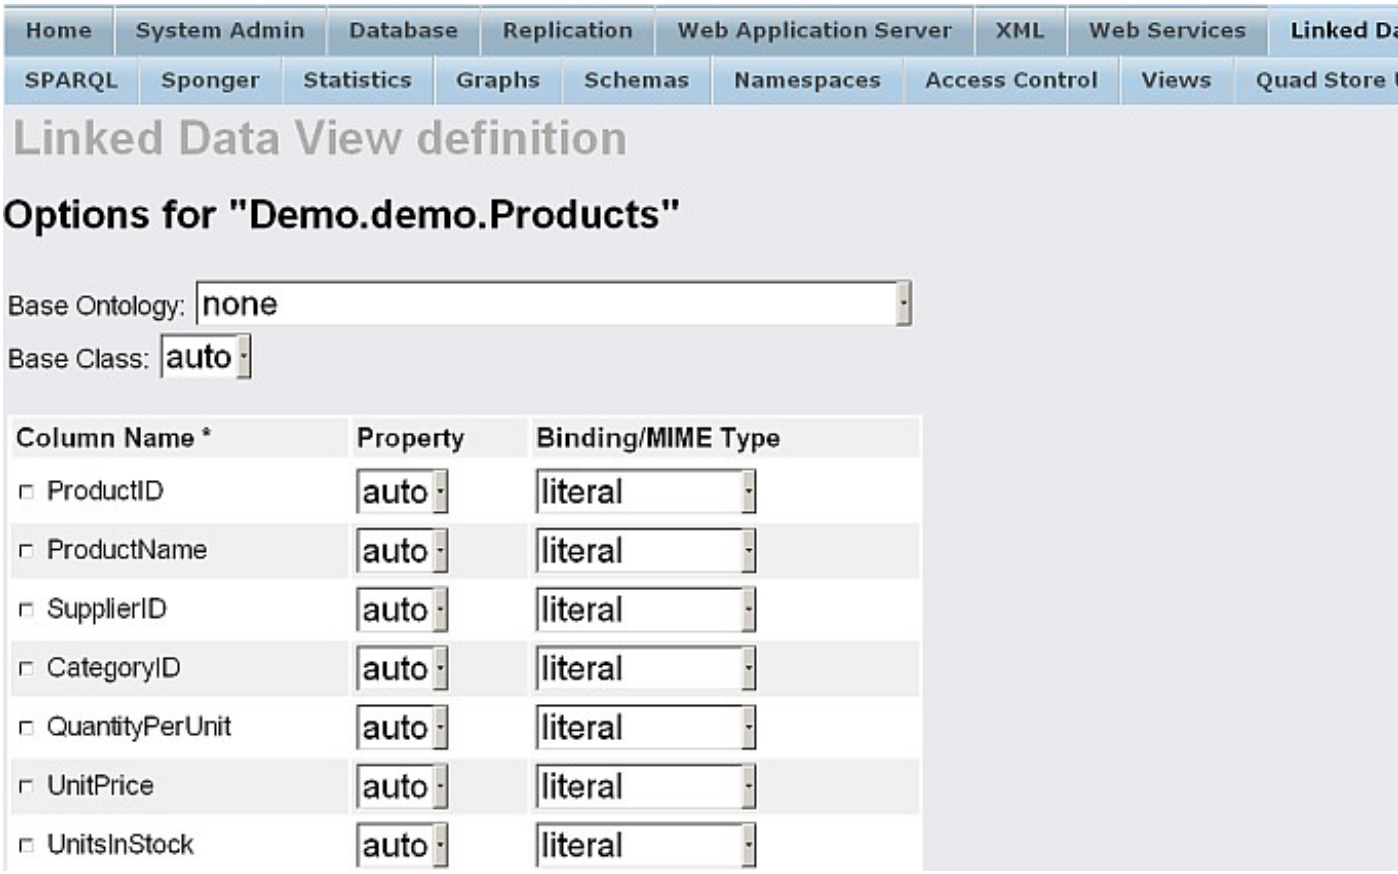
Figure 16.57. Column Selection



6. For images or other binary data in MIME formats to be revealed as anything other than generic "binary objects", you must map large varbinary types to the appropriate MIME types like image/gif. To do so, select the Edit link for Binding/MIME Type of the relevant table columns. You can:

    a. Leave the Binding/MIME Type literal; or
    b. Set to skip, such that the column will not be used in RDF generation; or
    c. Select the binary object value in order for the column to be referenced as binary.

Figure 16.58. Binding/MIME Types



7. After finishing with your changes click the Save button, or cancel the changes and go back by clicking the Cancel button.
8. Make sure you click the "Next" button.
9. At this point, the Linked Data View Definition form will let you Select Generation Targets options:

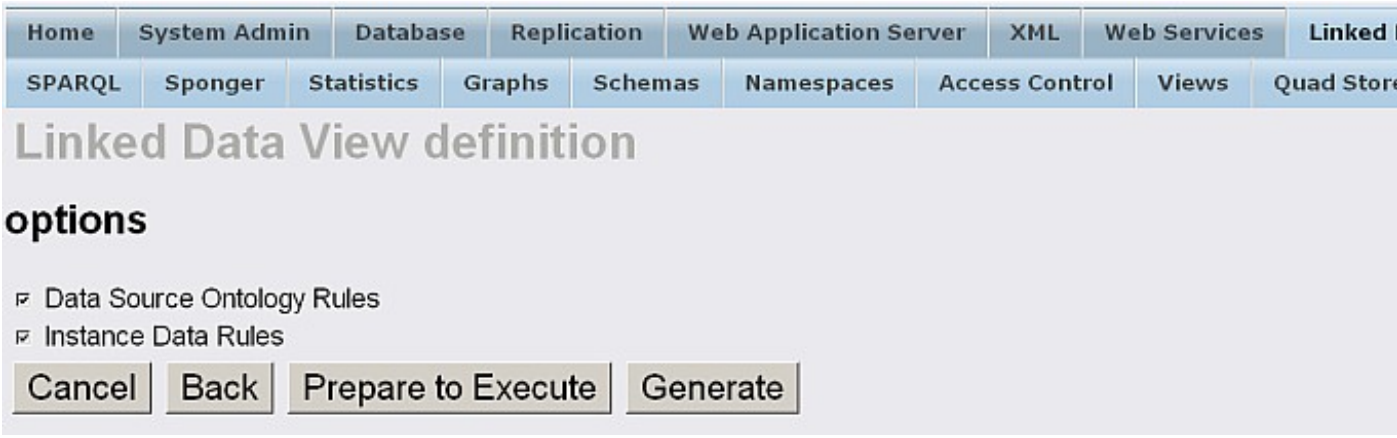
    a. Data Source Ontology Mappings
    b. Instance Data View Mappings
    c. VoID statistic

Figure 16.59. Generation Targets options

10. Make sure you click the "Next" button.
11. Based on your selections in the prior form, the Linked Data View Definition Deployment Options form will be offered:

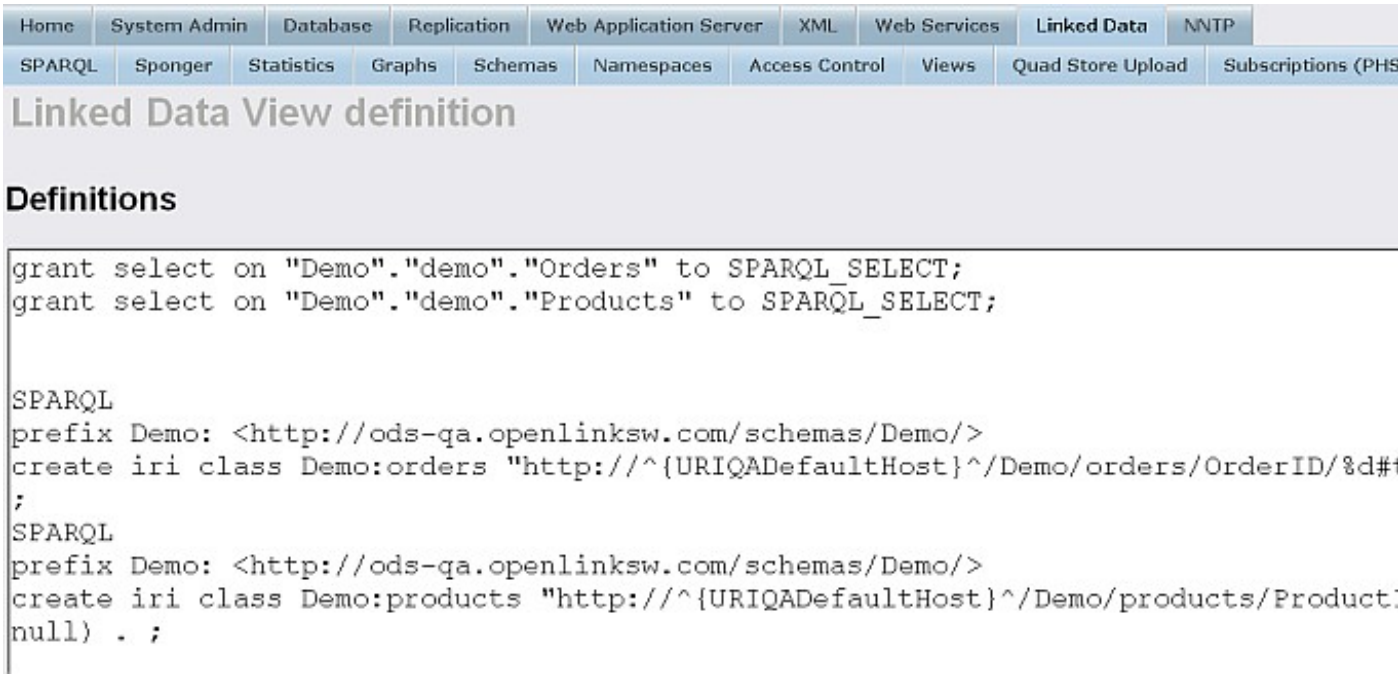
    a. Data Source Ontology Rules
    b. Instance Data Rules

Figure 16.60. Generation Targets options



12. Select the desired option(s) and click the "Prepare to Execute" button which unveils a generated Instance Data and/or Ontology form.

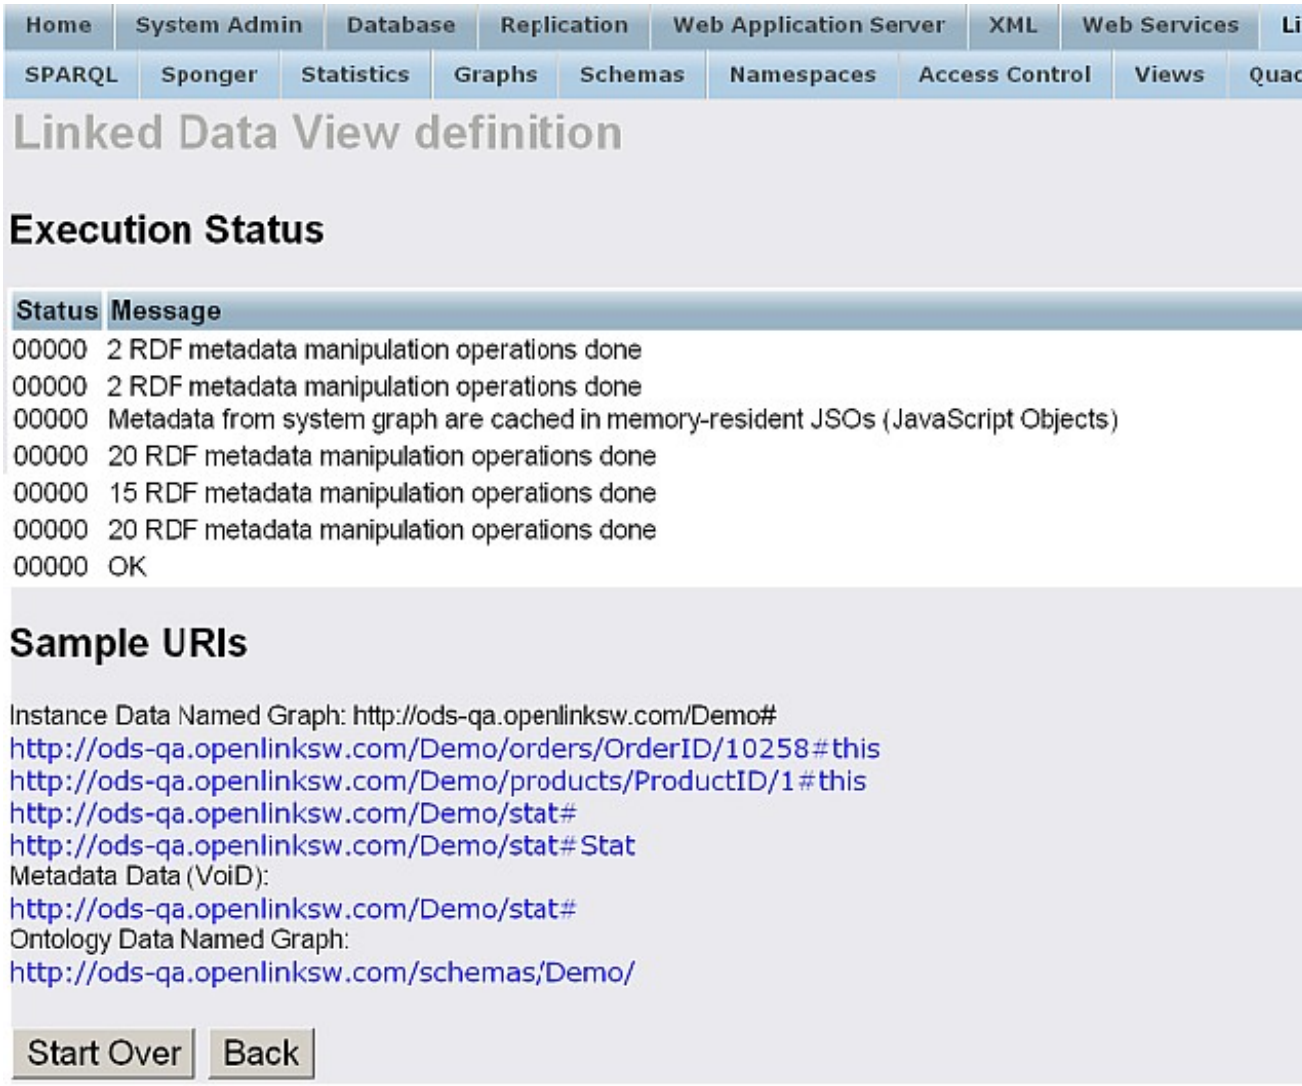
Figure 16.61. Instance Data and/or Ontology



13. Click the Execute button and Virtuoso will:

    a. Apply the generated declarations (instance data and ontology) to your Virtuoso instance
    b. Publish / Deploy declarations that expose the Wizard-generated Rewrite Rules and associated endpoints.

Figure 16.62. Publishing / Deployment declarations

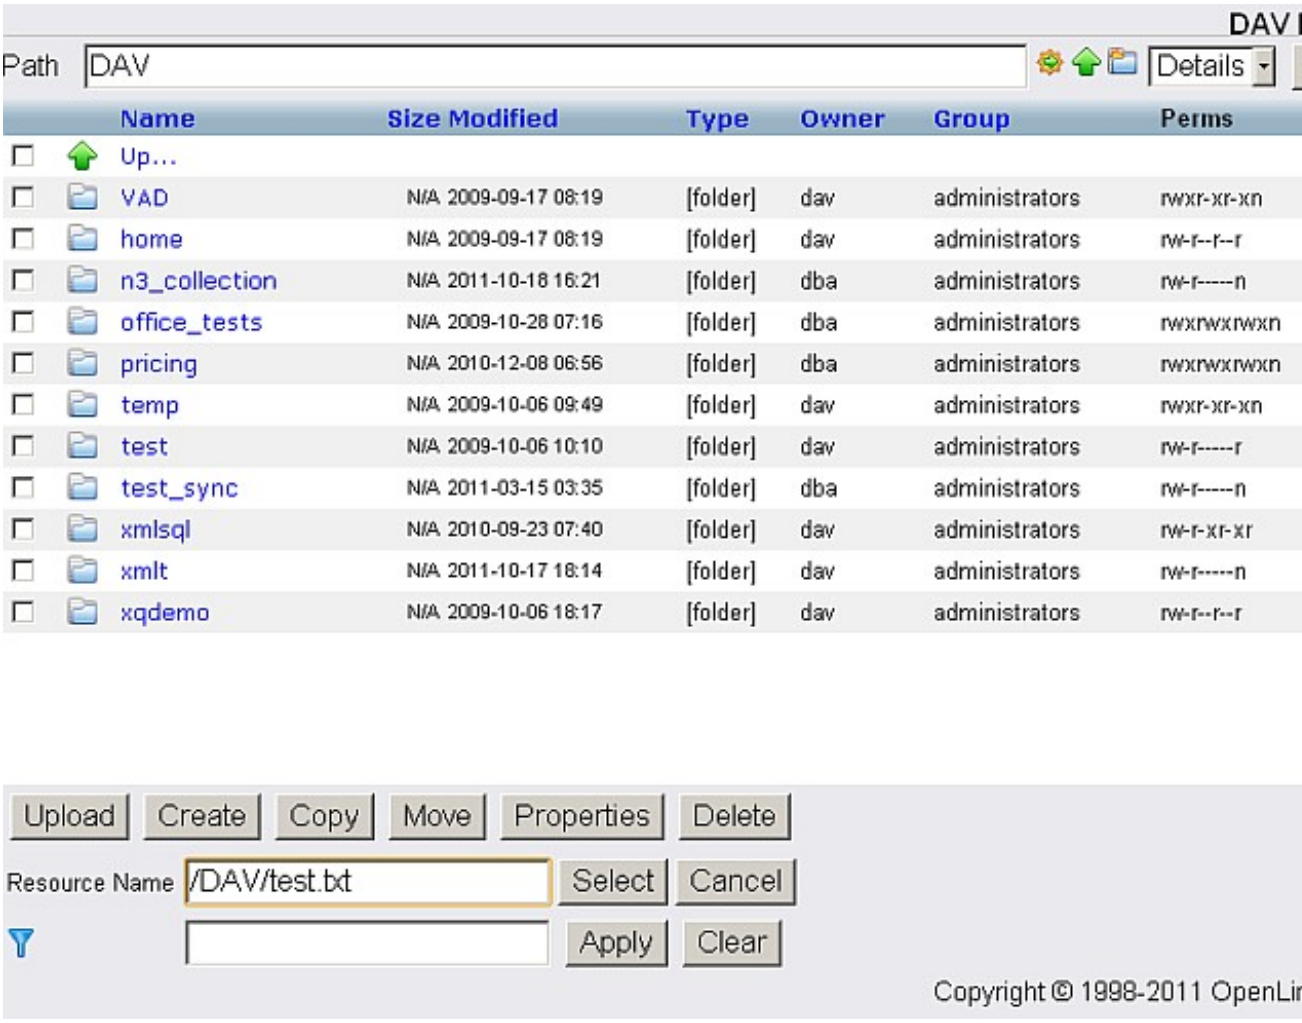


14. Optionally, you can also perform one of the following tasks:

    a. Save Data Mappings: when clicked, offers to save the generated Definitions to local file system
    b. Save Ontology Mappings: when clicked, offers to save the generated Ontology to local file system
    c. Export as WebDAV resource: exports the selected objects/items as a WebDAV resource:

        i. Click "Browse"
        ii. Enter a WebDAV resource and click the "Select" button.

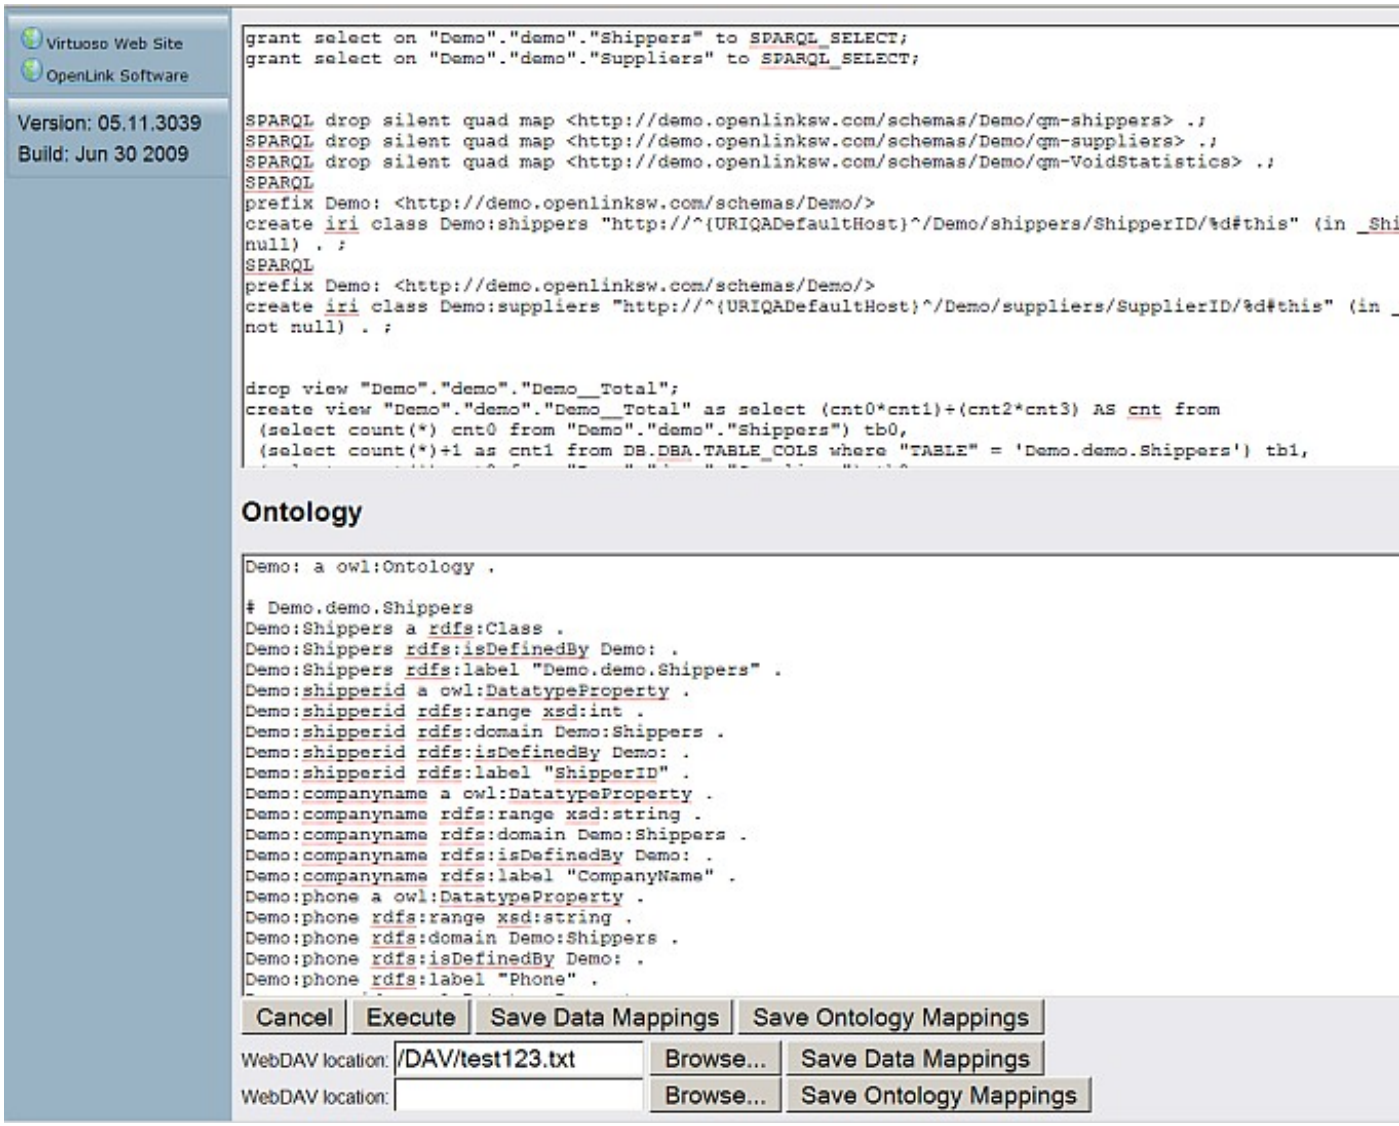
Figure 16.63. WebDAV resource



Note, the WebDAV resource path value will be shown in the WebDAV location field.

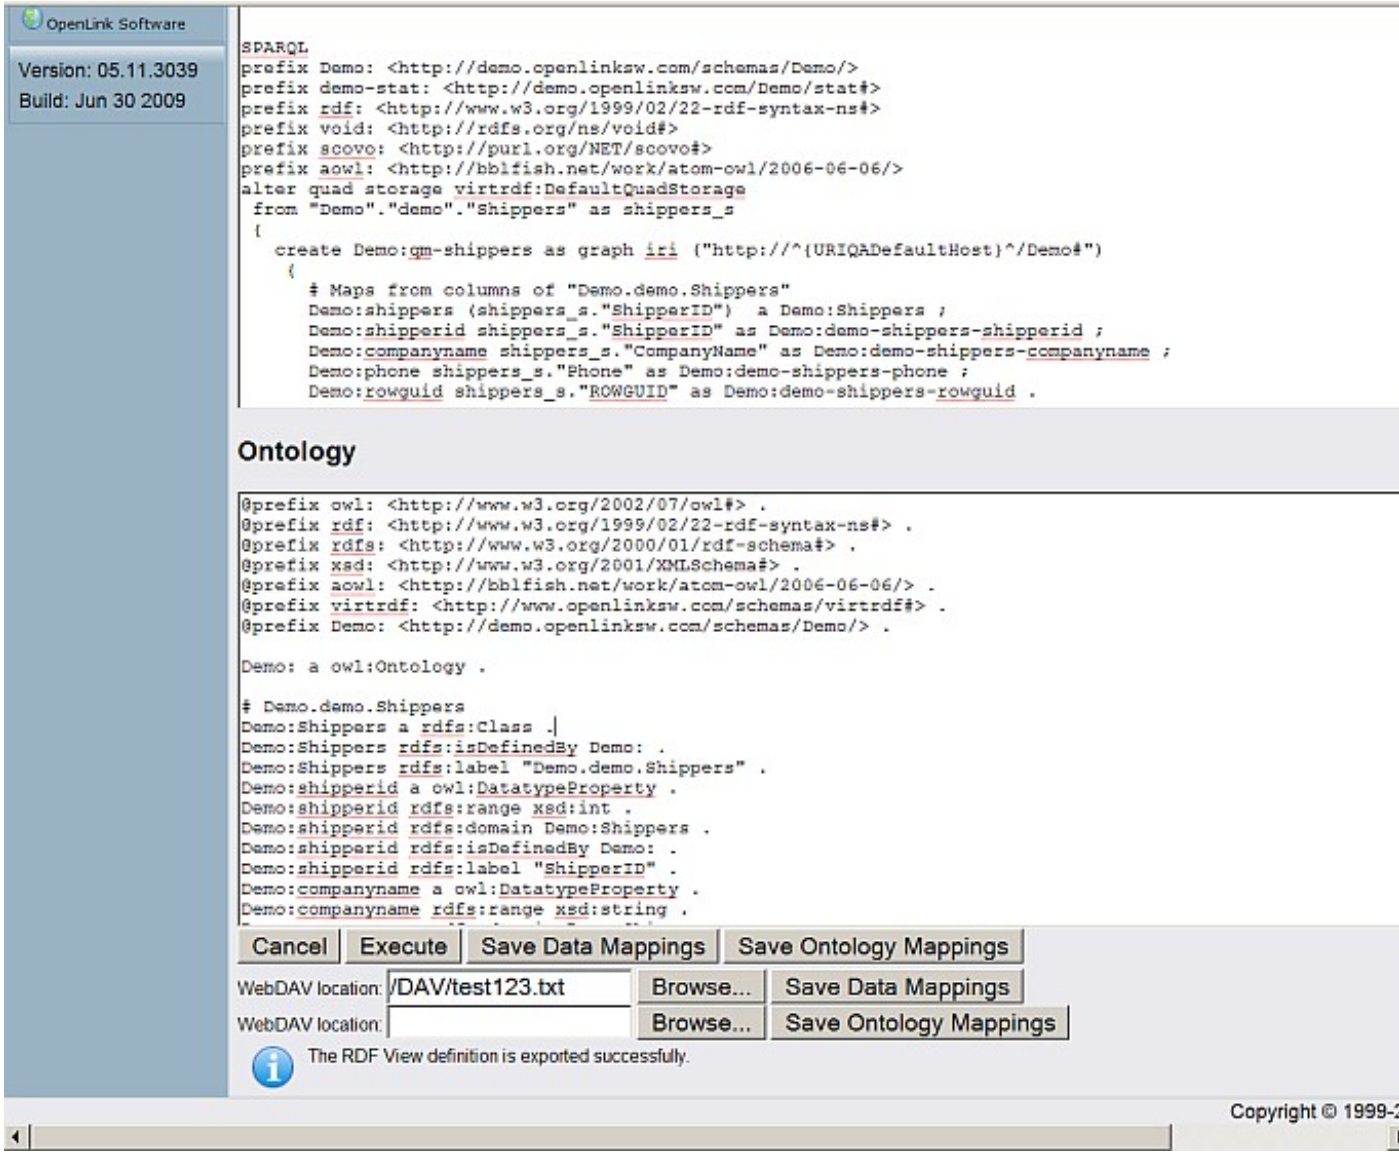
15. Then click the "Save Data Mappings" or "Save Ontology Mappings" button, to complete the option task of saving your generated (or edited) view declarations.

Figure 16.64. WebDAV resource



16. Error messages will be presented if the Wizard encounters problems. If there are no error messages, your Linked Data View declarations and Linked Data publishing activities will have completed successfully.

Figure 16.65. Linked Data View declarations and Linked Data publishing activities Finish



17. Click on Cancel to return to the initial Linked Data View Generation form.

16.6.4. Manual Linked Data Generation & Deployment using iSQL command-line

To generate data synchronization triggers and/or actual RDF quad store data from transient Linked Data views, one can use the Virtuoso built-in `RDF_VIEW_SYNC_TO_PHYSICAL()` function calling it from the iSQL command-line. See `more details and usage examples.`

16.7. Virtuoso R2RML Support

16.7.1. What is R2RML?

R2RML is a language for expressing customized mappings from relational databases to RDF data sets. Such mappings provide the ability to view existing relational data in the RDF data model, expressed in a structure and target vocabulary of the mapping author's choice.

R2RML mappings are themselves RDF graphs written in Turtle syntax.

16.7.2. Why use it?

As a W3C working draft, R2RML is becoming the generic standard adopted by most vendors of tools mapping relational data to RDF, enabling the interoperability of R2RML scripts, whether created with such tools or by hand.

16.7.3. How do I use it with Virtuoso?

Virtuoso has its own previously-developed proprietary equivalent of R2RML called Linked Data Views , which uses Virtuoso's Meta Schema Mapping Language to map relational data to RDF.

R2RML support is achieved by the inclusion of a simple translator which basically translates R2RML syntax to Virtuoso's own Linked Data Views syntax, which can then be executed to create the Linked Data Views themselves.

Install R2RML VAD package

First you will need to ensure you have the R2RML VAD package (rdb2rdf_dav.vad) installed.

Test with simple test script (basic.sql)

Having installed the R2RML VAD package, to test R2RML functionality, the easiest way is by executing a basic.sql script via the command line isql tool:

```
CREATE TABLE "R2RML"."TEST"."PRODUCT"(
  id integer primary key,
  name VARCHAR(100)
);

INSERT SOFT "R2RML"."TEST"."PRODUCT" VALUES (1, 'Virtuoso');

SPARQL CLEAR GRAPH <http://temp/product>;
SPARQL CLEAR GRAPH <http://example.com/>;

DB.DBA.TTLP ('
@prefix rr: <http://www.w3.org/ns/r2rml#> .
@prefix exa: <http://example.com/ns#> .
@prefix product: <http://example.com/product#> .

<http://example.com/ns#TriplesMap1>
    a rr:TriplesMap;

    rr:logicalTable
    [
      rr:tableSchema "R2RML";
      rr:tableOwner "TEST";
      rr:tableName  "PRODUCT"
    ];

    rr:subjectMap
    [
      rr:template "http://example.com/product/{id}";
      rr:class exa:product;
      rr:graph <http://example.com/>;
    ];

    rr:predicateObjectMap
    [
      rr:predicate product:id;
      rr:objectMap [ rr:column "id" ];
    ];

    rr:predicateObjectMap
    [
      rr:predicate product:name;
      rr:objectMap [ rr:column "name" ];
    ];
.
', 'http://temp/product', 'http://temp/product' )
;

--select DB.DBA.R2RML_TEST ('http://temp/product');

--DB.DBA.OVL_VALIDATE ('http://temp/product', 'http://www.w3.org/ns/r2rml#OVL');

-- Running the validation in order to find error in name of R2RML description graph
```

```
--DB.DBA.OVL_VALIDATE ('http://temp/product-nosuch', 'http://www.w3.org/ns/r2rml#OVL');

-- Running the validation in order to find error in name of R2RML metadata graph
--DB.DBA.OVL_VALIDATE ('http://temp/product', 'http://www.w3.org/ns/r2rml#OVL-nosuch');

--select DB.DBA.R2RML_EXECUTE ('http://temp/product');

exec ('sparql ' || DB.DBA.R2RML_MAKE_QM_FROM_G ('http://temp/product'));

--sparql select distinct ?g where { graph ?g { ?s a ?t }};

SPARQL
SELECT * FROM <http://example.com/>
WHERE {?s ?p ?o .};
```

1. First, copy basic.sql into:

   ```
   <VIRTUOSO_INSTALL>/bin/
   ```

2. Next, open Unix session or Windows Command Prompt and execute:

   ```
   cd <OPENLINK_INSTALL>/bin

   ./isql     (Unix)
   isql.exe   (Windows)

   OpenLink Interactive SQL (Virtuoso), version 0.9849b.
   Type HELP; for help and EXIT; to exit.
   SQL>
   ```

3. Then, within isql execute:

   ```
   SQL> load basic.sql;
   ```

4. Execution should finish with a simple SPARQL query that will return Linked Data for the test table created at the start of the script:

   ```
   s                              p                                                  o
   VARCHAR                        VARCHAR                                            VARCHAR
   _______________________________________________________________________________________________

   http://example.com/product/1   http://example.com/product#id                      1
   http://example.com/product/1   http://example.com/product#name                    Virtuoso
   http://example.com/product/1   http://www.w3.org/1999/02/22-rdf-syntax-ns#type    http://example.
   3 Rows. -- 0 msec.
   ```

Note : Subsequent executions of basic.sql will return an error since the test table will already exist. However, the remainder of the script will execute fine.

Examining basic.sql

1. We start by creating and populating the test table:

   ```
   CREATE TABLE "R2RML"."TEST"."PRODUCT"
     (
       id   INTEGER PRIMARY KEY ,
       name VARCHAR(100)
     );

   INSERT SOFT "R2RML"."TEST"."PRODUCT"
     VALUES
       (
         1, 'Virtuoso'
       );
   ```

2. Next we clear any graphs (temporary or permanent) that are to be used during this process:

   ```
   SPARQL CLEAR GRAPH <http://temp/product> ;
   SPARQL CLEAR GRAPH <http://example.com/> ;
   ```

3. Next we use the `DB.DBA.TTLP()` procedure to insert the R2RML into a temporary graph, <http://temp/product>:

   ```
   DB.DBA.TTLP
   ```

```
    (
      ' @prefix       rr:  <http://www.w3.org/ns/r2rml#>    .
        @prefix      exa:  <http://example.com/ns#>         .
        @prefix  product:  <http://example.com/product#>    .

        <http://example.com/ns#TriplesMap1>
            a                               rr:TriplesMap  ;

            rr:logicalTable
              [
                rr:tableSchema  "R2RML"    ;
                rr:tableOwner   "TEST"     ;
                rr:tableName    "PRODUCT"
              ];

            rr:subjectMap
              [
                rr:template  "http://example.com/product/{id}" ;
                rr:class     exa:product                       ;
                rr:graph     <http://example.com/>
              ];

            rr:predicateObjectMap
              [
                rr:predicate  product:id  ;
                rr:objectMap
                  [
                    rr:column  "id"
                  ];
              ];

            rr:predicateObjectMap
              [
                rr:predicate  product:name  ;
                rr:objectMap
                  [
                    rr:column "name"
                  ];
              ];
          .
      ',
      'http://temp/product',
      'http://temp/product'
    );
```

4. Next, there is a series of commented out lines that can be used for sanity checking:

```
--SELECT DB.DBA.R2RML_TEST ('http://temp/product');

--DB.DBA.OVL_VALIDATE ('http://temp/product', 'http://www.w3.org/ns/r2rml#OVL');

-- Running the validation in order to find error in name of R2RML description graph
--DB.DBA.OVL_VALIDATE ('http://temp/product-nosuch', 'http://www.w3.org/ns/r2rml#OVL');

-- Running the validation in order to find error in name of R2RML metadata graph
--DB.DBA.OVL_VALIDATE ('http://temp/product', 'http://www.w3.org/ns/r2rml#OVL-nosuch');

--SELECT DB.DBA.R2RML_EXECUTE ('http://temp/product');
```

5. Next, DB.DBA.R2RML_MAKE_QM_FROM_G() is used to perform the conversion from R2RML into Virtuoso's own Linked Data Views script. The output is then prepended with the keyword 'SPARQL' and a space, and executed using `exec()`:

```
EXEC ('SPARQL ' || DB.DBA.R2RML_MAKE_QM_FROM_G ('http://temp/product'));
```

Note : The final triples are placed in the graph defined in the R2RML script itself (<http://example.com/>)

Alternatively, the destination graph can be specified as an optional second parameter of DB.DBA.R2RML_MAKE_QM_FROM_G():

```
DB.DBA.R2RML_MAKE_QM_FROM_G
  (
    (
```

```
    IN g VARCHAR
  [, IN target_graph VARCHAR := NULL]
   )
)
```

6. Finally, a simple SPARQL statement is executed to prove data is returned:

```
SPARQL
  SELECT *
  FROM <http://example.com/>
  WHERE {?s ?p ?o .};
```

16.7.4. Known Limitations

rr:sqlQuery is not currently supported, due to limitations in the optimizer used for Virtuoso's native implementation of Linked Data Views.

16.7.5. Generating an R2RML based Linked Data View from iSQL command-line

Using Virtuoso you can programmatically generate Linked Data Views atop Relational Data Sources, using R2RML via the built-in function: *R2RML_GENERATE_LINKED_VIEW* function. In order to use this function, you need to have the rdb2rdf_dav.vad package installed.

```
R2RML_GENERATE_LINKED_VIEW
  (
    in source varchar,
    in destination_graph varchar,
    in graph_type int default 0,
    in clear_source_graph int default 1
  )
```

Here is detailed description of the funcion's parameter:

- *source*

  : The source R2RMLdocument URI. Acceptable schemes include: file:, dav:, http: and https:. These are also acceptable as source graph URI;
- *destination graph*

  : This is a default graph name (an IRI) applicable to either virtual or physical graph.
- *graph_type*

  : 0 - virtual; 1 - physical graph which sets the actual graph type;
- *clear_source_graph*

  : Determines if existing R2RML source graphs (those holding view declarations) are replaced as part of processing pipeline.

Note : The R2RML mapping script may have a triples like:

```
[] rr:graph <graph_name>
```

and in this case they take precedence and virtual graph would be defined as in the R2RML. If so, then if destination graph is specified as physical, all virtual graphs found in the R2RML would go in the destination_graph.

Usage Example

1. Ensure the R2RML VAD package rdb2rdf_dav.vad is installed.
2. To clear out existing mappings execute:

```
SQL> SELECT RDF_VIEW_DROP_STMT_BY_GRAPH ('http://example.com');
VARCHAR
_______________________________________________________________________________
```

```
SPARQL drop silent quad map <http://demo.openlinksw.com/r2rmldemo.n3> .;

1 Rows. -- 16 msec.

SQL> SPARQL DROP SILENT QUAD MAP <http://demo.openlinksw.com/r2rmldemo.n3> ;

STATE    MESSAGE
VARCHAR  VARCHAR
_______________________________________________________________________________

00000    Quad map <http://demo.openlinksw.com/r2rmldemo.n3> is no longer used in storage <http://w
>
00000    Quad map <http://demo.openlinksw.com/r2rmldemo.n3> is deleted
00000    Transaction committed, SPARQL compiler re-configured
00000    2 RDF metadata manipulation operations done

4 Rows. -- 406 msec.

SQL> SPARQL CLEAR <http://demo.openlinksw.com/r2rmldemo.n3>;

callret-0
VARCHAR
_______________________________________________________________________________

Clear <http://demo.openlinksw.com/r2rmldemo.n3> -- done

1 Rows. -- 15 msec.

SQL> DROP TABLE "R2RML"."TEST"."PRODUCT" ;

Done. -- 0 msec.

SQL> CREATE TABLE "R2RML"."TEST"."PRODUCT"
(
  "id" INTEGER,
  "name" VARCHAR(100),
  PRIMARY KEY ("id")
);
Done. -- 16 msec.
```

3. Insert sample data into a Table by executing:

```
SQL> INSERT SOFT "R2RML"."TEST"."PRODUCT" VALUES(1, 'Virtuoso');
Done. -- 0 msec.
```

4. Locate or create your R2RML mapping document, for example: .n3 file with the following content:

```
@prefix rr: <http://www.w3.org/ns/r2rml#> .
@prefix exa: <http://example.com/ns#> .
@prefix product: <http://example.com/product#> .

<http://example.com/ns#TriplesMap1>
    a rr:TriplesMap;

    rr:logicalTable
    [
      rr:tableSchema "R2RML";
      rr:tableOwner "TEST";
      rr:tableName  "PRODUCT"
    ];

    rr:subjectMap
    [
      rr:template "http://example.com/product/{id}";
      rr:class exa:product;
    ];

    rr:predicateObjectMap
    [
      rr:predicate product:id;
      rr:objectMap [ rr:column "id" ];
    ];

    rr:predicateObjectMap
    [
```

```
      rr:predicate product:name;
      rr:objectMap [ rr:column "name" ];
    ];
.
```

5. Generate a Linked Data View from the R2RML document that applies to the sample data (created earlier) by executing the statement:

```
SQL> DB.DBA.R2RML_GENERATE_LINKED_VIEW('http://demo.openlinksw.com/r2rmldemo.n3', 'http://example.
STATE    MESSAGE
VARCHAR  VARCHAR
_______________________________________________________________________________

00000    IRI class <r2rml:virt02-8513ca7e0ce41d2e38f0c750fd552139> has been defined (inherited fro
00000    Literal class <r2rml:virt02-daca9ceddea29d53dbbdb6bd0f3dee68> has been defined (inherited
00000    Quad storage <http://www.openlinksw.com/schemas/virtrdf#DefaultQuadStorage> is flagged as

00000    Quad storage <http://www.openlinksw.com/schemas/virtrdf#DefaultQuadStorage> is unflagged
00000    Transaction committed, SPARQL compiler re-configured
00000    9 RDF metadata manipulation operations done

10 Rows. -- 1109 msec.
SQL>
```

6. Verify successful creation of the Linked Data View by executing the following SPARQL query via iSQL or Conductor interface:

```
SQL> SPARQL
SELECT *
FROM <http://example.com>
WHERE {?s ?p ?o} ;

s                              p                                                o
VARCHAR                        VARCHAR                                          VARCHAR
_______________________________________________________________________________

http://example.com/product/1   http://example.com/product#id                    1
http://example.com/product/1   http://example.com/product#name                  Virtuoso
http://example.com/product/1   http://www.w3.org/1999/02/22-rdf-syntax-ns#type  http://exampl

3 Rows. -- 15 msec.
```

16.7.6. Virtuoso Conductor R2RML Import Wizard

The Virtuoso Conductor can be used for importing existing R2RML scripts into Virtuoso and generate the necessary RDF Linked Data Views for Virtuoso hosting and deployment.

Usage Example

1. Ensure the R2RML rdb2rdf_dav.vad and latest Conductor conductor_dav.vad VAD packages are installed.
2. Create a test table with sample data:

```
SQL> CREATE TABLE "R2RML"."TEST"."PRODUCT"
(
  "id" INTEGER,
  "name" VARCHAR(100),
  PRIMARY KEY ("id")
);
Done. -- 16 msec.
SQL> INSERT SOFT "R2RML"."TEST"."PRODUCT" VALUES(1, 'Virtuoso');
Done. -- 0 msec.
SQL> INSERT SOFT "R2RML"."TEST"."PRODUCT" VALUES(2, 'UDA');
Done. -- 0 msec.
SQL>
```

3. Grant select privileges on the "R2RML"."TEST"."PRODUCT" table to the SPARQL user to enable execution via SPARQL endpoint:

```
SQL> GRANT SELECT ON R2RML.TEST.PRODUCT  TO "SPARQL", "SPARQL_UPDATE"
Done. -- 1 msec.
```

4. Create the following R2RML mapping script for the "R2RML"."TEST"."PRODUCT" table:

```
$ cat demo.n3
@prefix rr: <http://www.w3.org/ns/r2rml#> .
@prefix exa: <http://example.com/ns#> .
@prefix product: <http://example.com/product#> .

<http://example.com/ns#TriplesMap1>
    a rr:TriplesMap;

    rr:logicalTable
    [
      rr:tableSchema "R2RML";
      rr:tableOwner "TEST";
      rr:tableName  "PRODUCT"
    ];

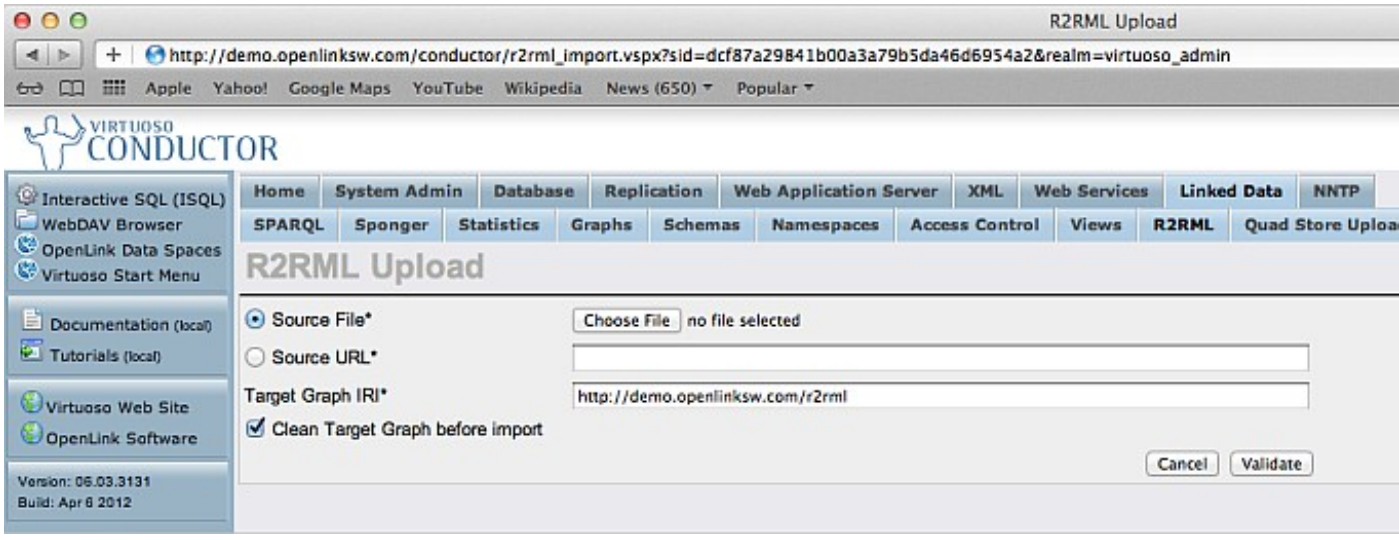
    rr:subjectMap
    [
      rr:template "http://example.com/product/{id}";
      rr:class exa:product;
    ];

    rr:predicateObjectMap
    [
      rr:predicate product:id;
      rr:objectMap [ rr:column "id" ];
    ];

    rr:predicateObjectMap
    [
      rr:predicate product:name;
      rr:objectMap [ rr:column "name" ];
    ];
.
$
```

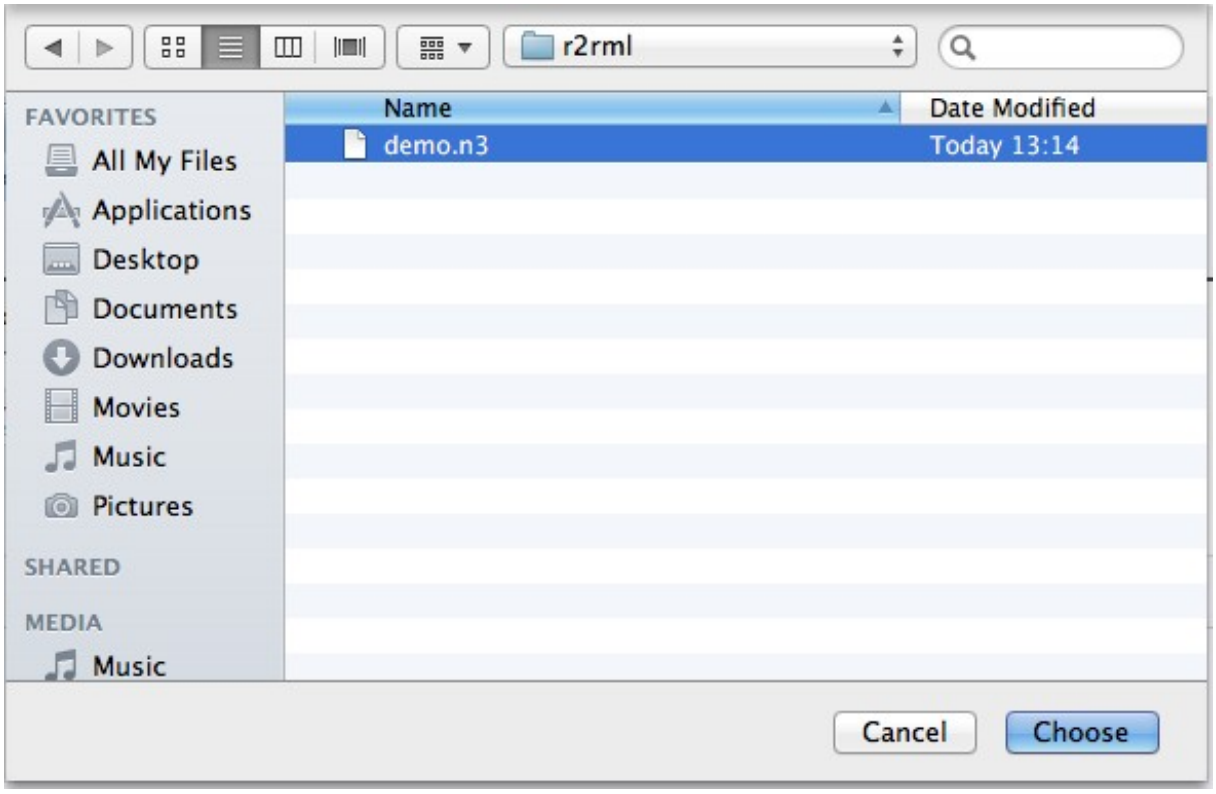
5. Got to the Linked Data -> R2RML tab of the Virtuoso Conductor:

Figure 16.66. Conductor R2RML Import Wizard



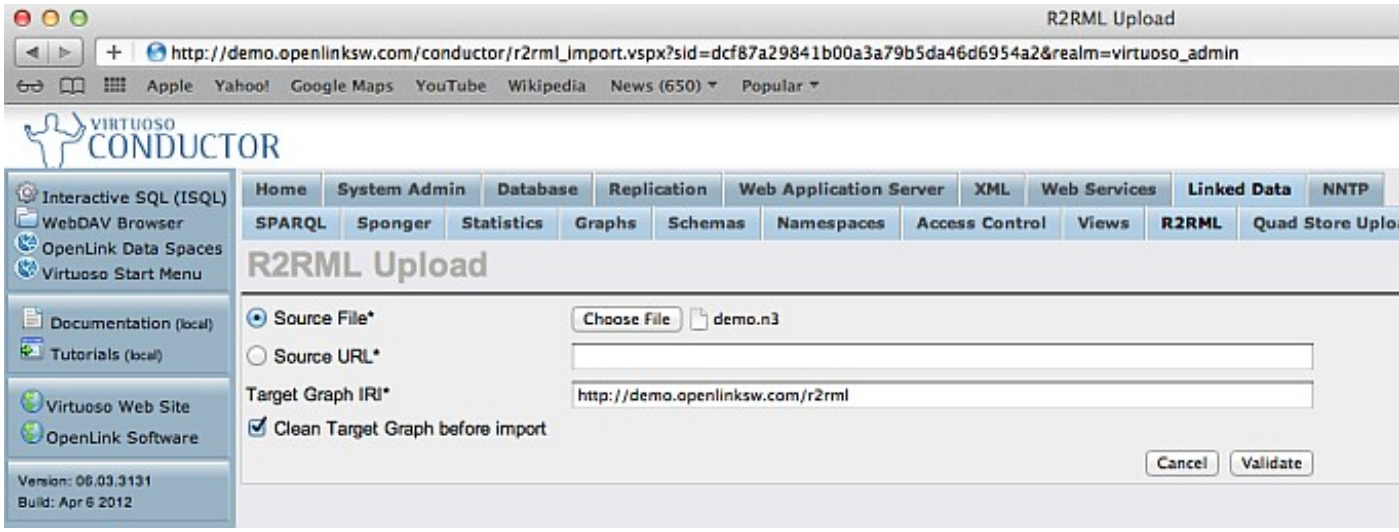
6. Select the Choose File button and select the R2RML file to load:

Figure 16.67. Conductor R2RML Import Wizard



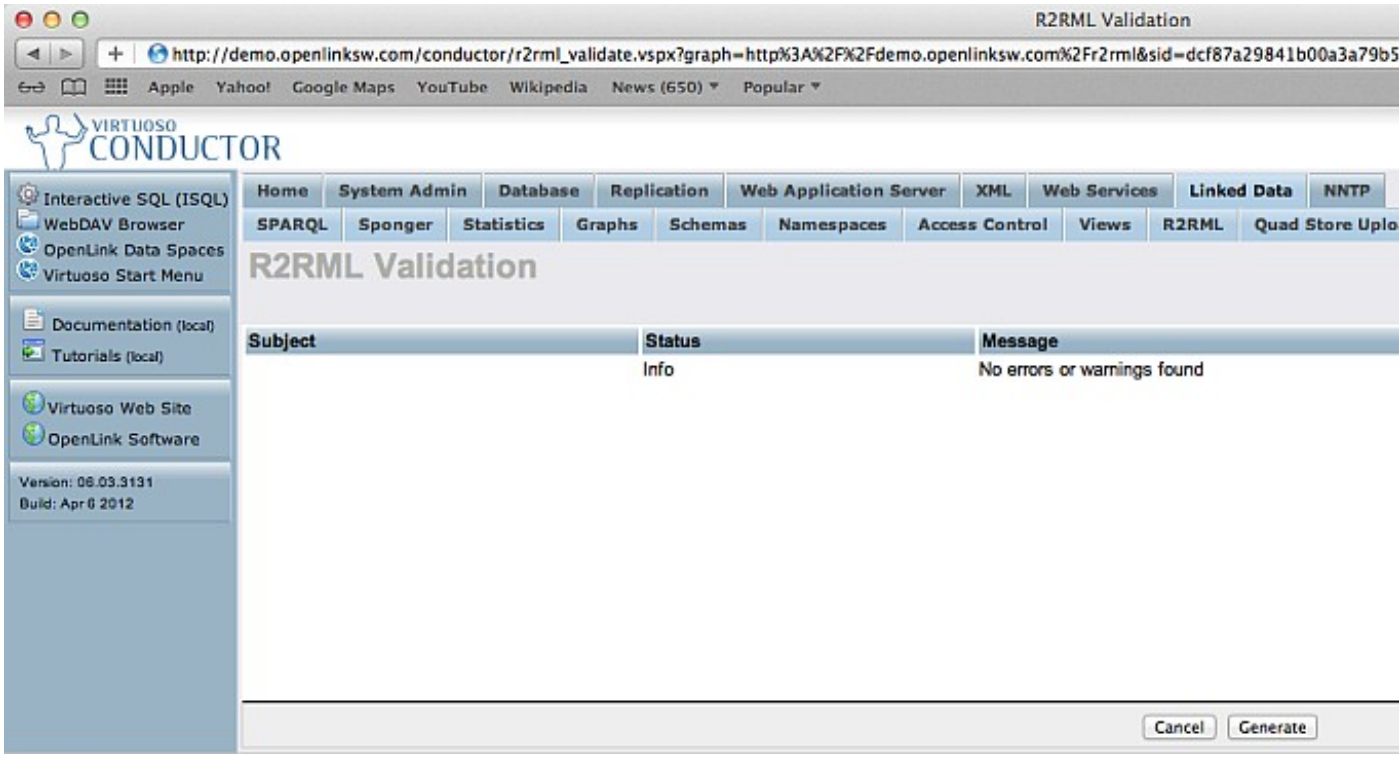
7. Select the Validate button to verify the R2RML mapping script:

Figure 16.68. Conductor R2RML Import Wizard



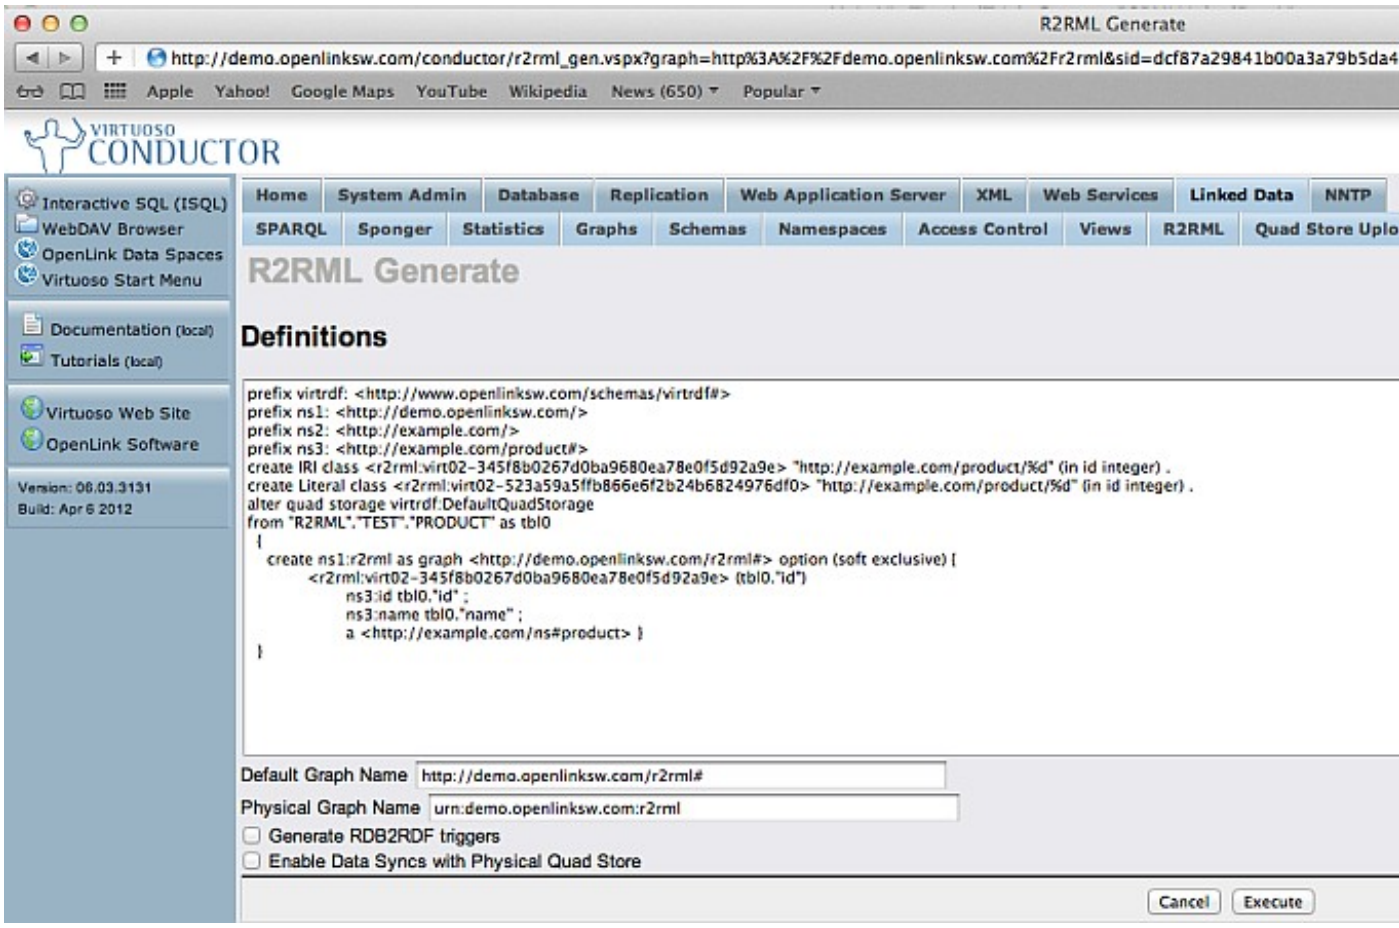
8. Select the Generate button to generate the RDF Linked Data Views mappings for the R2RML mapping script:

Figure 16.69. Conductor R2RML Import Wizard



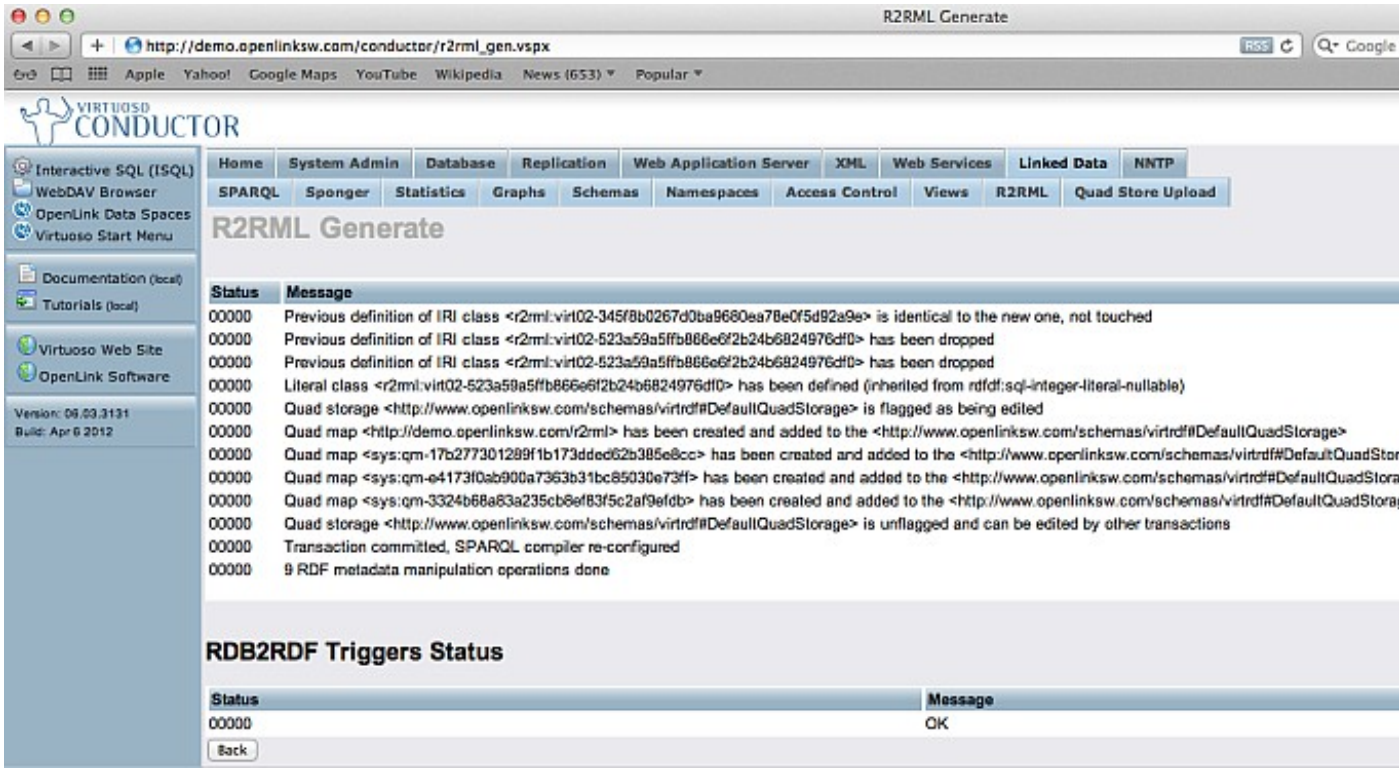
9. Select the Execute button to create the RDF Linked Data Views mapping the the Quad Store:

Figure 16.70. Conductor R2RML Import Wizard



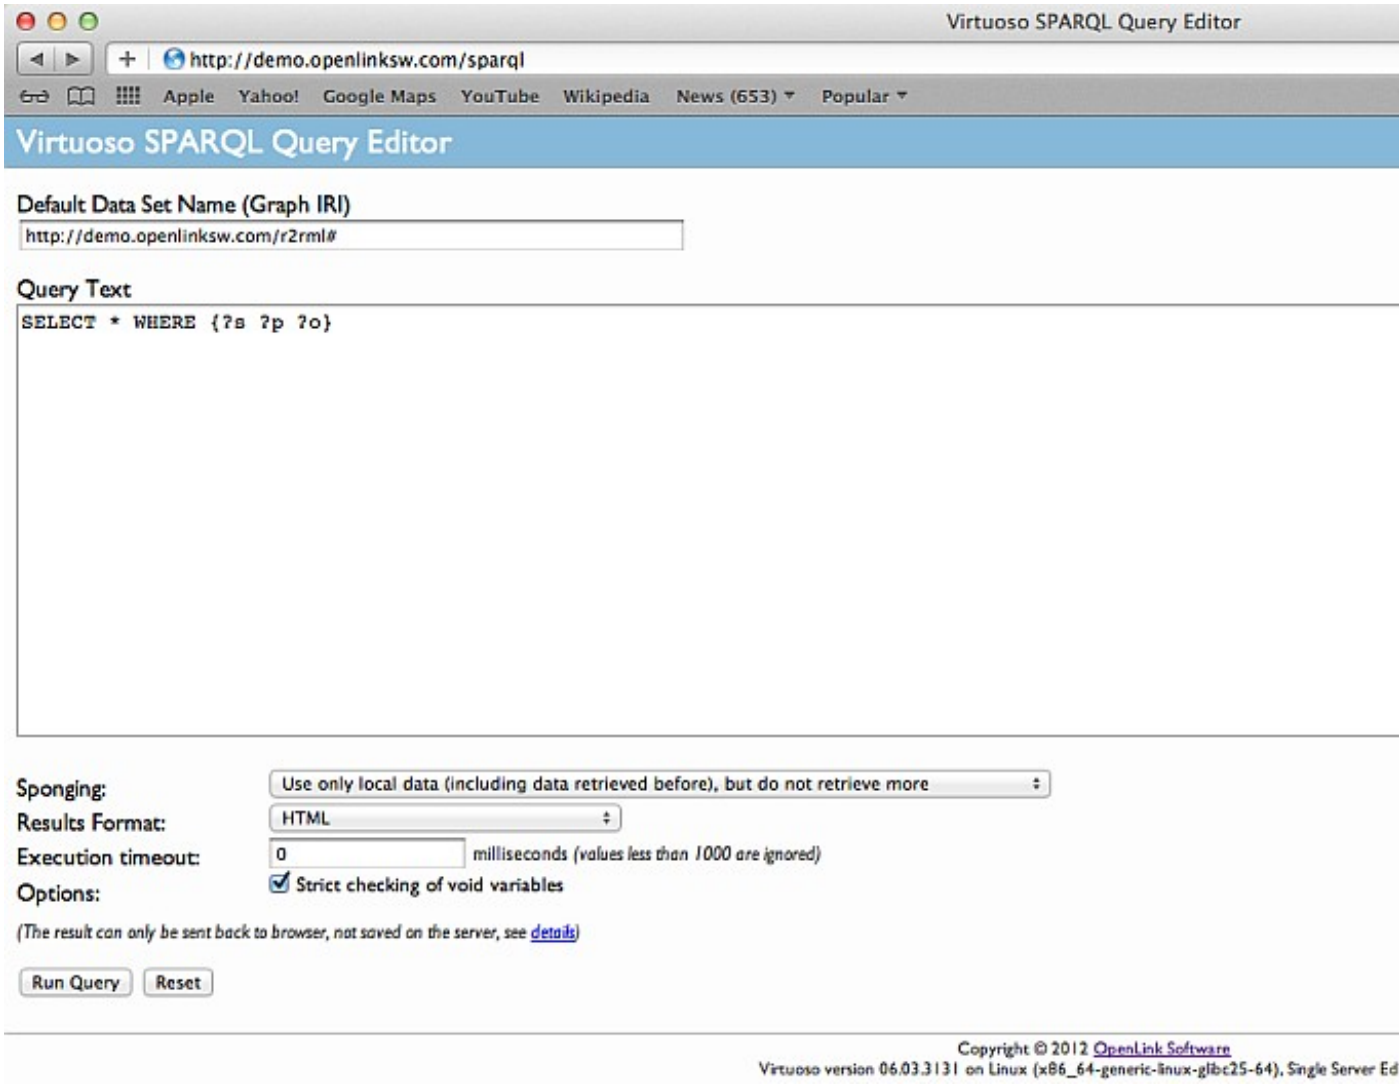
10. The RDF Linked Data View creation is complete and status is displayed:

Figure 16.71. Conductor R2RML Import Wizard



11. The Default Graph Name (transient) specified http://demo.openlinksw.com/r2rml# can now be used to run a SPARQL query against the created Linked Data View. If the Generate RDB2RDF triggers and Enable Data Syncs with Physical Quad Store check boxes are selected the Physical Graph Name (persistent) specified urn:demo.openlinksw.com/r2rml# can be used to run a SPARQL query against the materialized triples in the Quad Store.

Figure 16.72. Conductor R2RML Import Wizard



12. The results set for the Linked Data View graph are displayed:

Figure 16.73. Conductor R2RML Import Wizard

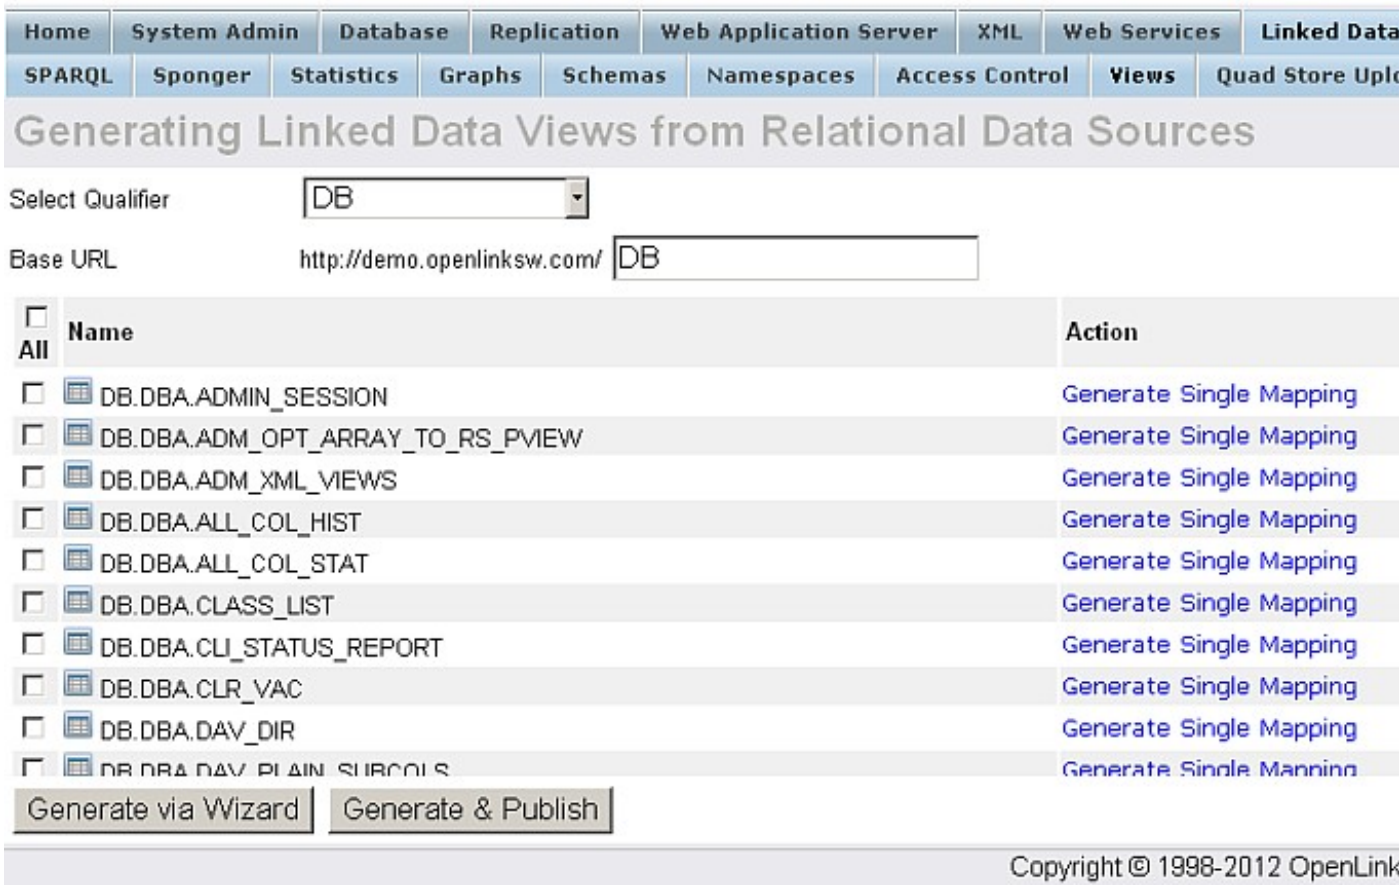
16.7.7. Generate Transient and/or Persistent Linked Data Views atop Remote Relational Data Sources Using Conductor

This section describes how you can generate R2RML Scripts from Linked Data Views, using the Virtuoso Conductor ODBC or JDBC accessible.

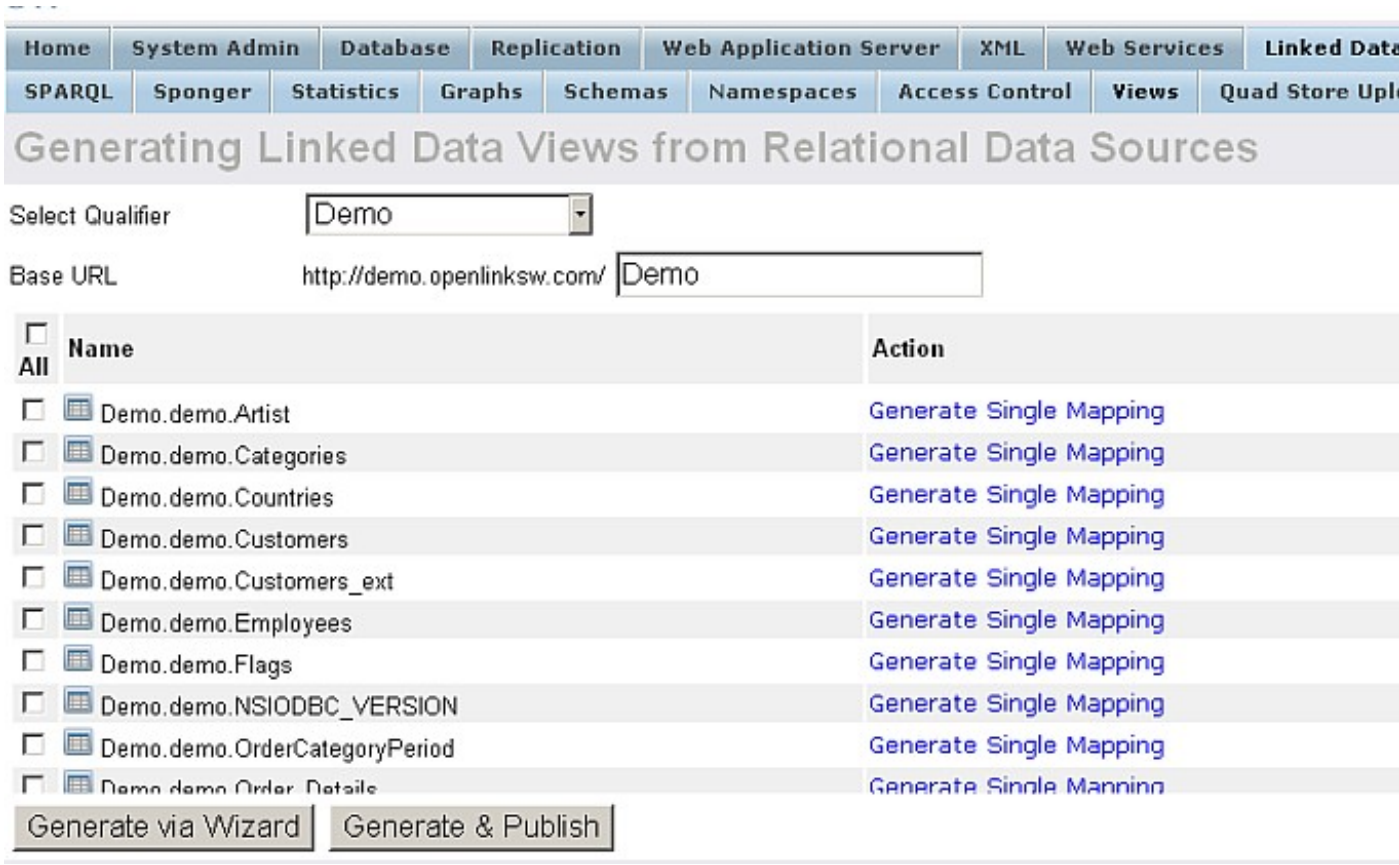
1. Ensure you have installed Conductor conductor_dav.vad VAD package with version 1.32.38 or higher.
2. Go to http://<cname>[:<port>]/conductor.
3. Enter dba credentials.
4. Go to Linked Data -> Views:

Figure 16.74. Generating Transient and/or Persistent Linked Data Views



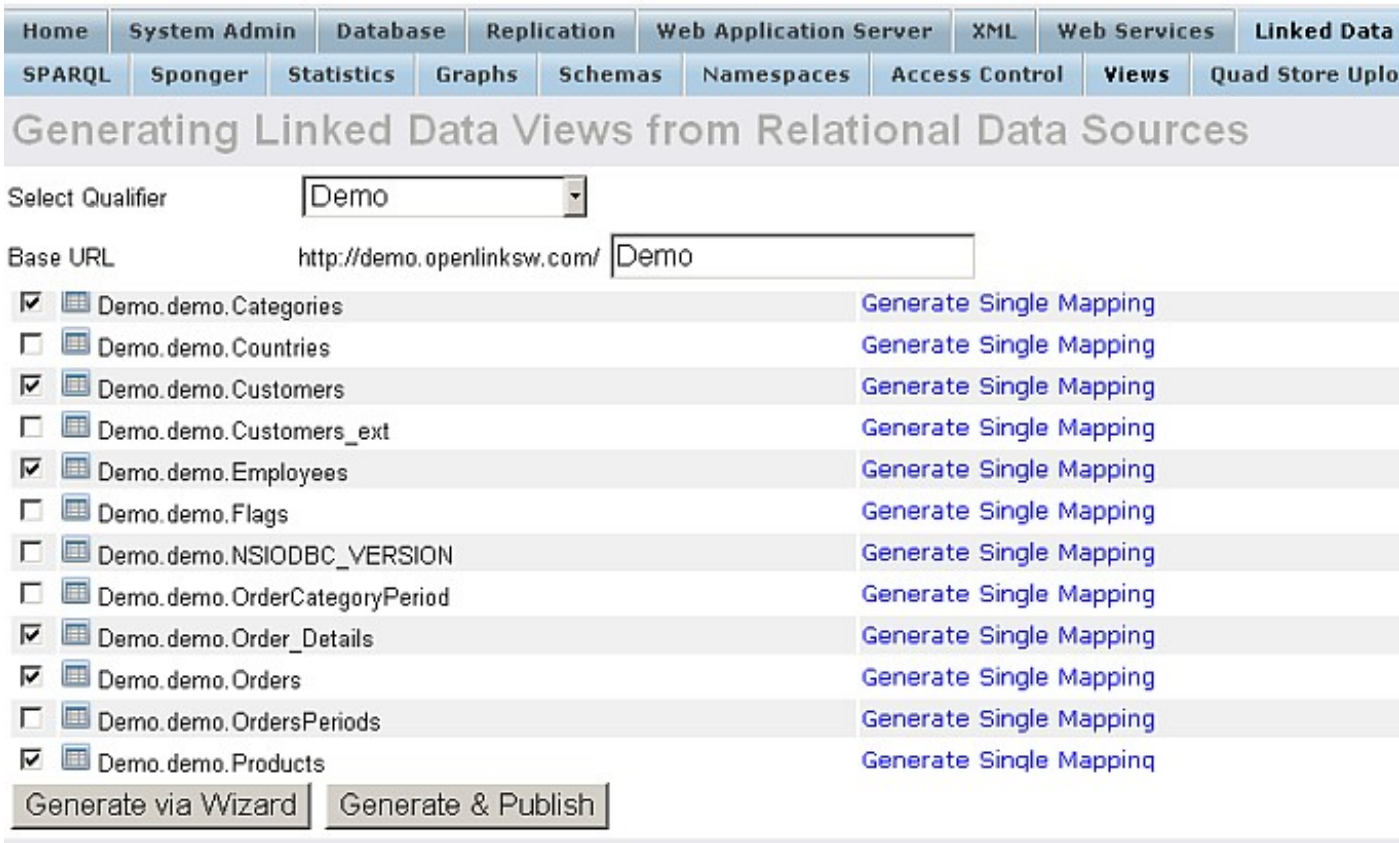
5. Select Qualifier Demo:

Figure 16.75. Generating Transient and/or Persistent Linked Data Views



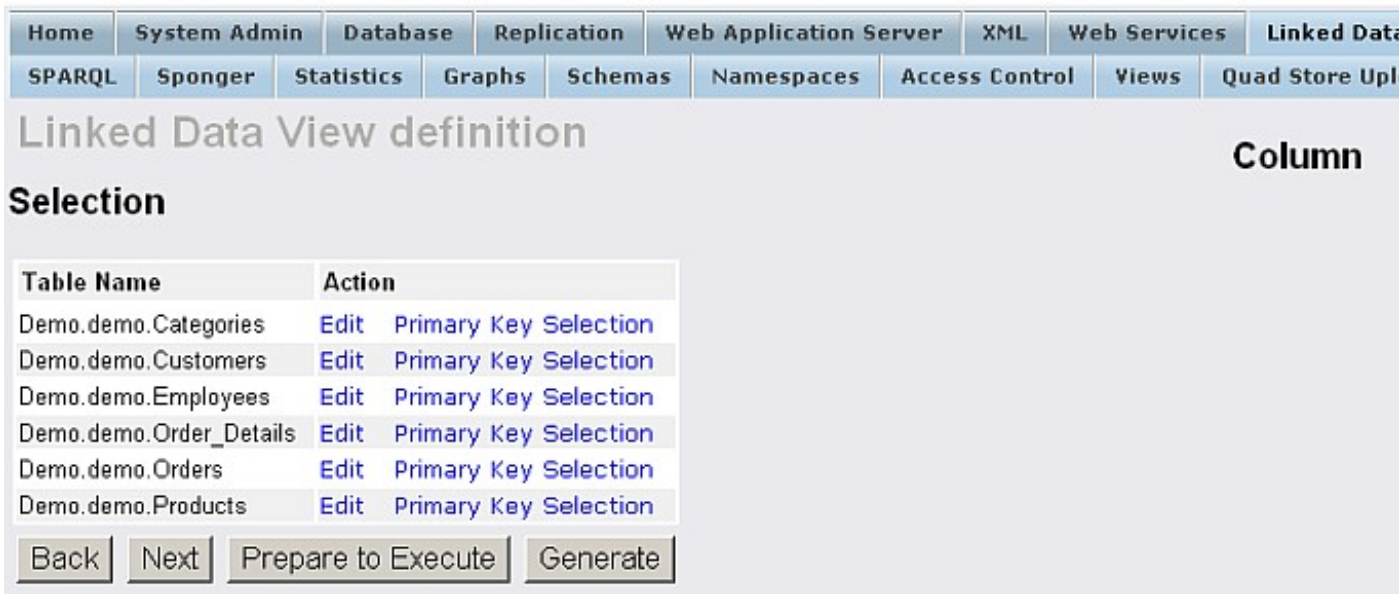
6. Select table(s) by hatching the check-box to the left of the table name; for example, select the following tables from the Northwind DB: Categories, Customers, Employees, Order_Details, Orders, Products .

Figure 16.76. Generating Transient and/or Persistent Linked Data Views



7. Click Generate via Wizard:

Figure 16.77. Generating Transient and/or Persistent Linked Data Views



8. Click Prepare to Execute.
9. The R2RML script for the selected table(s) will be generated and displayed in the R2RML Graph text-area:

Figure 16.78. Generating Transient and/or Persistent Linked Data Views

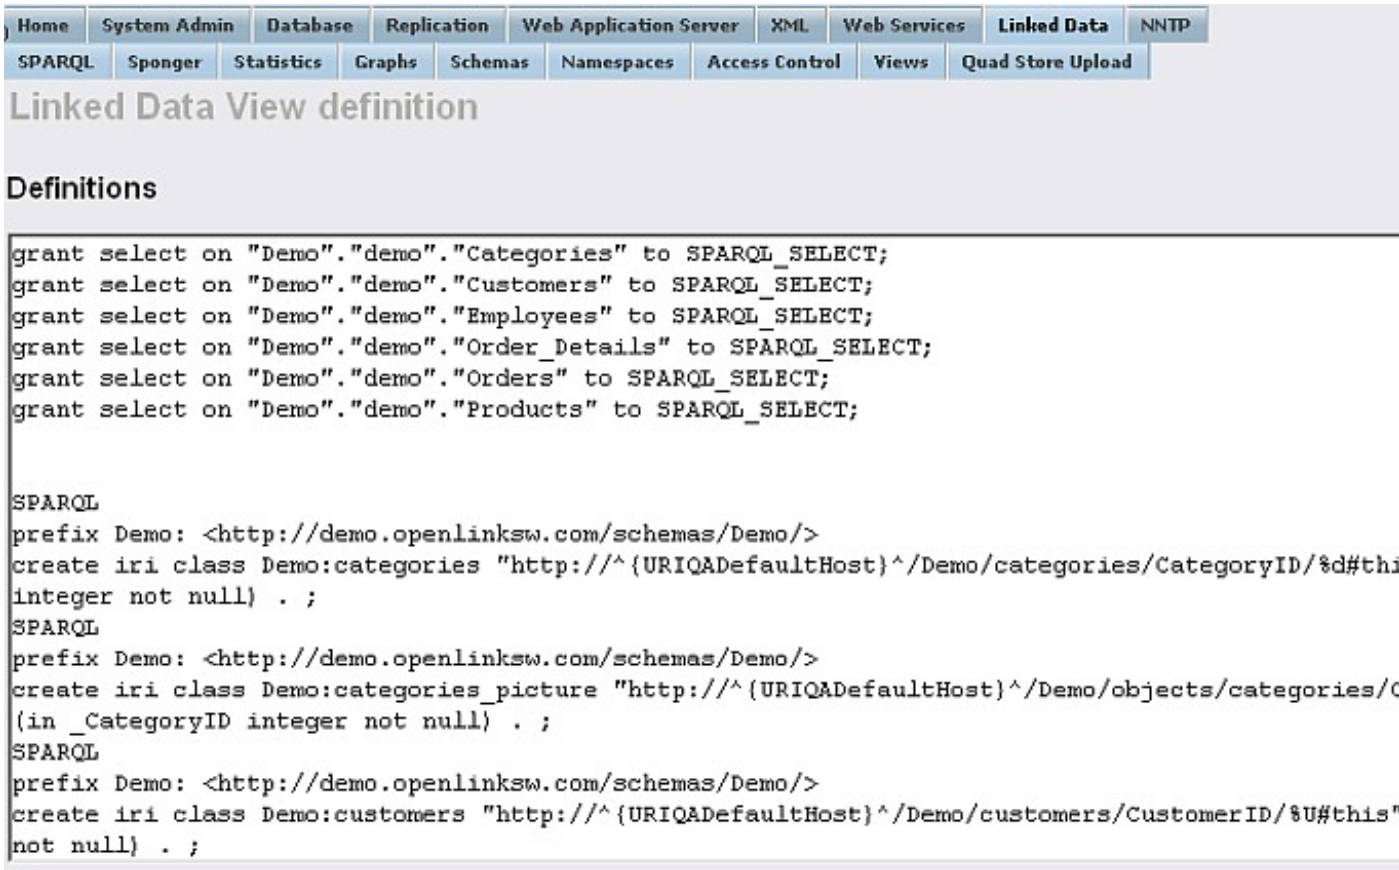


Figure 16.79. Generating Transient and/or Persistent Linked Data Views

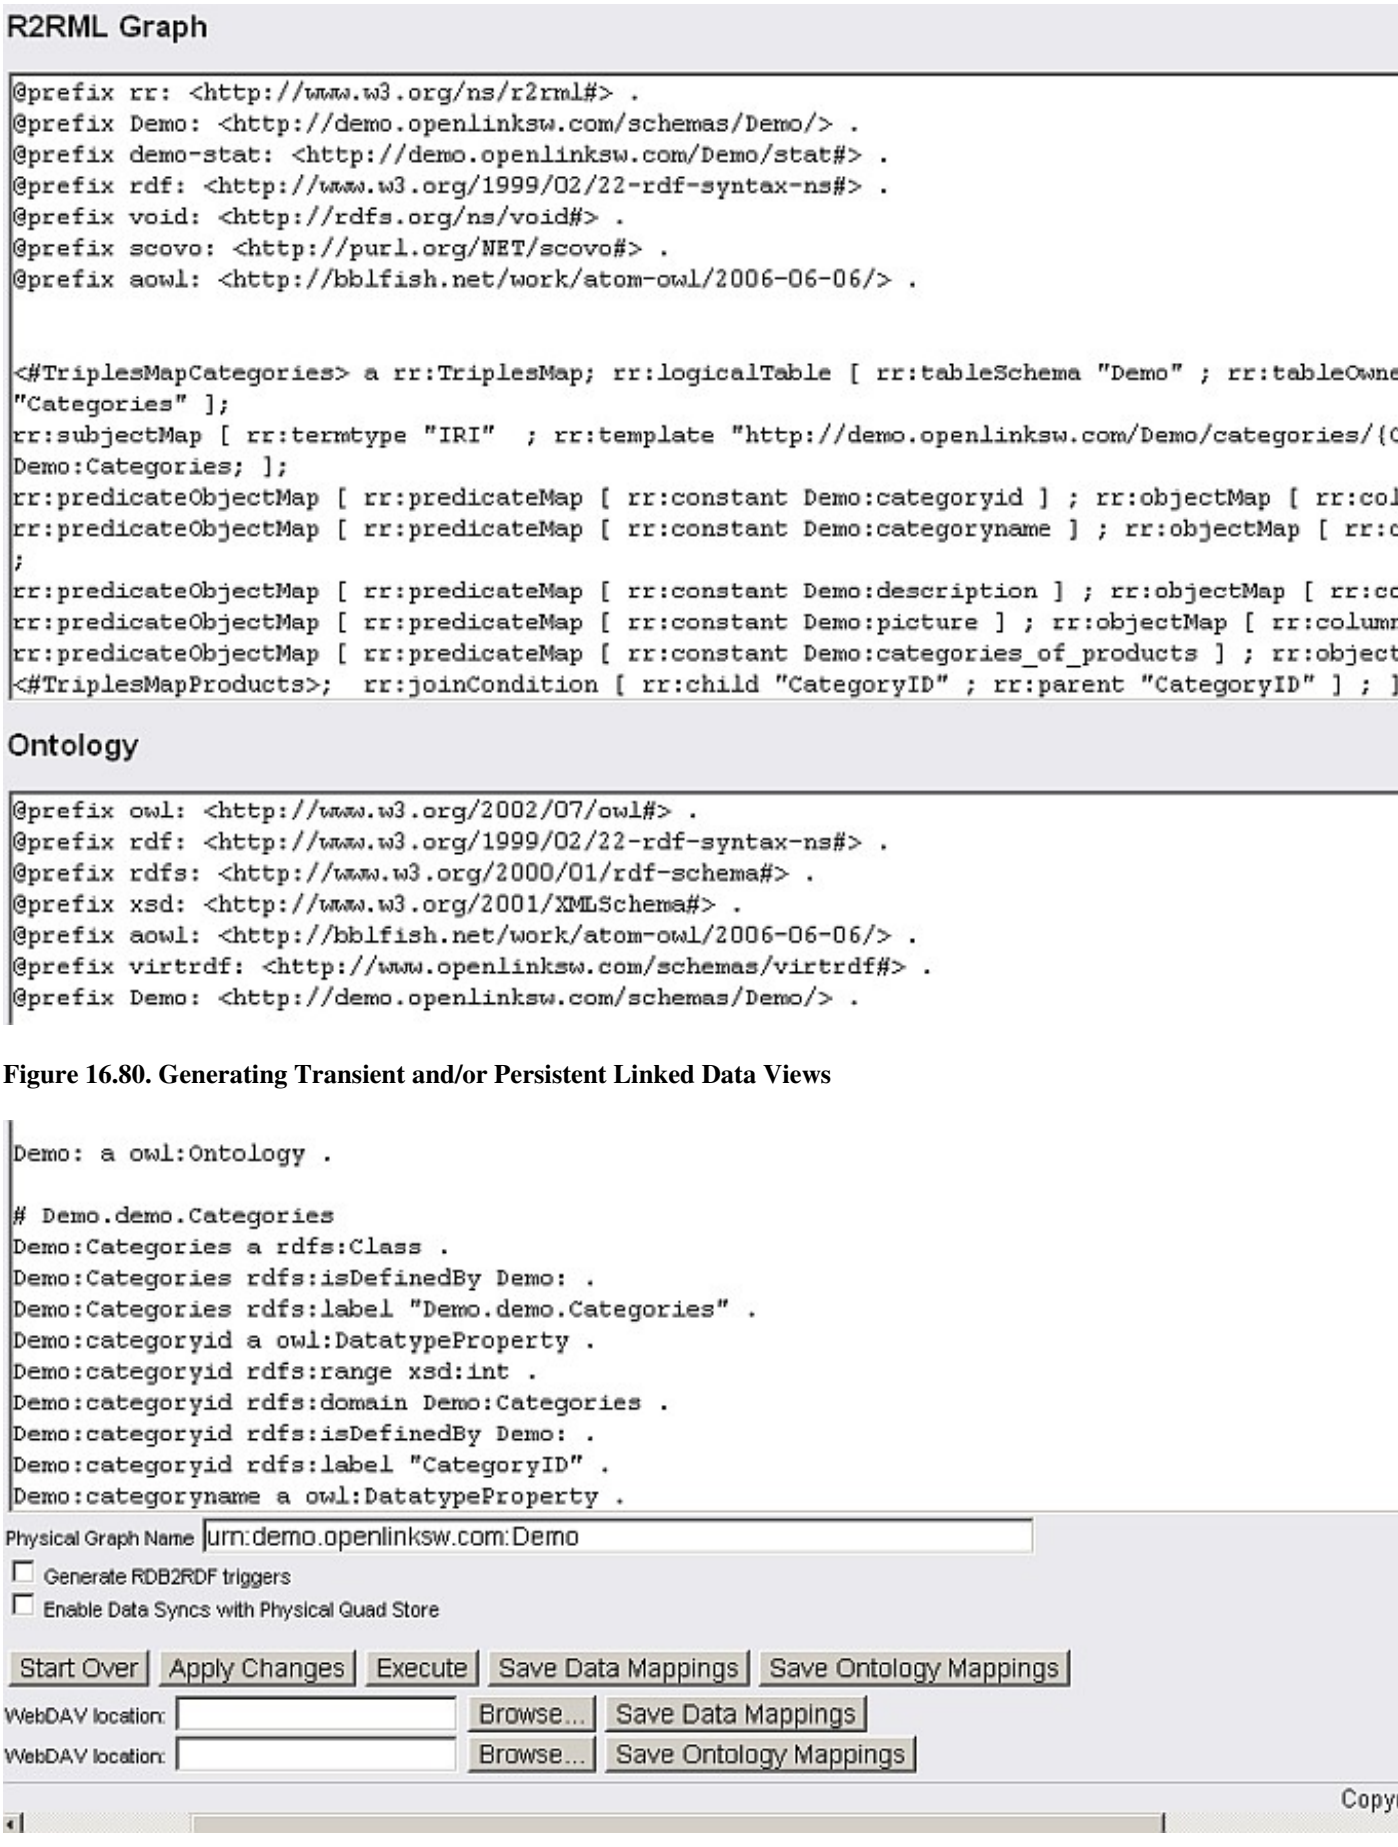

Figure 16.80. Generating Transient and/or Persistent Linked Data Views

10. As result the following R2RML script should be generated for the Northwind DB collection:

```
@prefix rr: <http://www.w3.org/ns/r2rml#> .
```

```
@prefix Demo: <http://demo.openlinksw.com/schemas/Demo/> .
@prefix demo-stat: <http://demo.openlinksw.com/Demo/stat#> .
@prefix rdf: <http://www.w3.org/1999/02/22-rdf-syntax-ns#> .
@prefix void: <http://rdfs.org/ns/void#> .
@prefix scovo: <http://purl.org/NET/scovo#> .
@prefix aowl: <http://bblfish.net/work/atom-owl/2006-06-06/> .

16.8. Examples of Linked Data Views

16.8.1. Simple Mapping Example -- Northwind Linked Data View

Here is example of the basic Northwind Linked Data Views deployment. The sequence of operations is very common for adding SPARQL access to existing application.

There exist few important questions to answer. Who should have access to data behind Linked Data View? Should someone have access to other sorts of RDF data but not to the new View? What are applications that should be interoperable with the new RDF data source? Are there any applications that produce similar data but that data sould be kept apart from data made by view? How to ensure that deployment the view will not cause problems for other applications?

First of all, we decide whether the default web service endpoint should have access to the data in question. If it should then we have to grant SELECT privileges to the account "SPARQL" that is used for the default endpoint; if it should not but some custom edpoint should then grant to the owner account of that account. Granting access is less trivial that it is usual. On one hand, those who can make SQL SELECT statements on application's tables can also make SPARQL queries on Linked Data View over that tables, because it makes SQL inside. On the other hand, those who do not intend to query that data at all may get unexpected "permission denied" errors on queries that worked fine before adding an Linked Data View. If SPARQL compiler can not prove that the query can not access data from the view then it will generate SQL code that will access tables behind the view. In some cases permission problems should be resolved by creating Linked Data View in a separate RDF storage . In this example, data are public:

```
use DB;

GRANT SELECT ON "Demo"."demo"."Products" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Suppliers" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Shippers" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Categories" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Customers" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Employees" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Orders" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Order_Details" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Countries" TO "SPARQL";
GRANT SELECT ON "Demo"."demo"."Provinces" TO "SPARQL";
```

Interoperability is the next question. The example is not interoperable with anything so in can provide data of any form, a real application will probably use some ontology from external source. Sometimes data should be converted from internal application's representation to something different (such as metric to imperial or ATT country code to two-character country id); sometimes composed IRIs should follow special rules; function-based IRI classes may help in that cases. As this is the first example, only plain format-string-based IRI classes are used.

We should also ensure that data generated by the new view will not be accidentally mixed with other data of the database. For that purpose the example will use a unique graph name that includes both application name and host name. In addition, the script will drop declarations that might remain from a previous run of the same script. The script is executed many times during the

development so erasing previous version is worth writing. It will report an error if there's nothing to erase but it's better than unpredictable errors due to writing new declarations over existing ones.

Note

Making graph name unique for every host is not needed if the application is supposed to be "local" and nobody will access more than one installation of the application. If this is the case, use some fixed graph IRI, not necessarily starting with hostname at all; this is much more convenient for querying because you don't have to calculate the graph name in each query. With fixed graph in use, it is still possible to clone the Linked Data View to map to a unique graph as soon as the application become "public" and requires merging data from many installations.

```
SPARQL drop quad map graph iri("http://^{URIQADefaultHost}^/Northwind")
;
SPARQL drop quad map virtrdf:NorthwindDemo
;
```

The *{URIQADefaultHost}* macro is replaced with the value of *DefaultHost* parameter of [URIQA] section of configuration file. The IRI is written as *iri("http://^{URIQADefaultHost}^/Northwind")* , not as *<http://^{URIQADefaultHost}^/Northwind>* because macro of this sort works only inside SPARQL string values.

Now it's safe to create IRI classes needed for the view. If these classes are used only in the view we define then it is safe to create all of them in a single statement. If some of them are used across multiple declarations then errors may occur. it is impossible to redefine an IRI class that is in use; the compiler will try to avoid reporting errors by checking whether the new declaration is identical to the existing one and by trying garbage collection in hope that the IRI class is used only in garbage, but errors may occur anyway. Thus it is better to declare "shared" IRI classes by individual statements and group together only "private" IRI classes of a view. If a "class redefinition" error occurs in the middle of a group then "undefined class" errors may occur after because the processing of the group was interrupted before rest of group was not executed. When in trouble, try `DB.DBA.RDF_AUDIT_METADATA` procedure.

```
SPARQL
create iri class northwind:Category "http://^{URIQADefaultHost}^/Northwind/Category/%d#this" (in category
create iri class northwind:Shipper "http://^{URIQADefaultHost}^/Northwind/Shipper/%d#this" (in shipper_id
create iri class northwind:Supplier "http://^{URIQADefaultHost}^/Northwind/Supplier/%d#this" (in supplier
create iri class northwind:Product   "http://^{URIQADefaultHost}^/Northwind/Product/%d#this" (in product_
create iri class northwind:Customer "http://^{URIQADefaultHost}^/Northwind/Customer/%U#this" (in customer
create iri class northwind:Employee "http://^{URIQADefaultHost}^/Northwind/Employee/%U%U%d#this" (in empl
create iri class northwind:Order "http://^{URIQADefaultHost}^/Northwind/Order/%d#this" (in order_id integ
create iri class northwind:CustomerContact "http://^{URIQADefaultHost}^/Northwind/CustomerContact/%U#this
create iri class northwind:OrderLine "http://^{URIQADefaultHost}^/Northwind/OrderLine/%d/%d#this" (in ord
create iri class northwind:Province "http://^{URIQADefaultHost}^/Northwind/Province/%U/%U#this" (in count
create iri class northwind:Country "http://^{URIQADefaultHost}^/Northwind/Country/%U#this" (in country_na
create iri class northwind:Flag "http://^{URIQADefaultHost}^%U#this" (in flag_path varchar not null) .
create iri class northwind:dbpedia_iri "http://dbpedia.org/resource/%U" (in uname varchar not null) .
create iri class northwind:EmployeePhoto "http://^{URIQADefaultHost}^/DAV/VAD/demo/sql/EMP%d#this" (in em
create iri class northwind:CategoryPhoto "http://^{URIQADefaultHost}^/DAV/VAD/demo/sql/CAT%d#this" (in ca
;
```

One IRI class per subject type; format strings begin with same host but different directory names so this will let the compiler to guess the type of subject by the text of IRI. Most of declarations are bijections and may get *option (bijection)* hint but these format strings are so simple that the compiler may understand it by itself. (*northwind:Employee* is not a bijection because `sprintf_inverse` will be unable to split the tail of IRI string and find the boundary between first and last name.)

The final operation is extending the default quad storage with new tree of quad map patterns.

```

The created Linked Data View is sufficient for querying relational data via SPARQL but not for accessing data by dereferencing IRIs of subjects. Making IRIs dereferenceable requires configuring HTTP server; that is explained in second part of the example .

16.8.2. BSBM to RDF

This section includes example mapping SQL Data to RDF for BSBM.

Each BSBM installation includes a demonstration database that includes a simple management system schema and instance data. This sample database provides an easy route for introducing BSBM users and developers to the virtues of RDF based Linked Data Views built atop existing BSBM relational databases.

```

16.8.6. Musicbrainz to RDF

The following code creates the Musicbrainz Linked Data Views Deployment and Demo Scripts:

```
create text index on ZITGIST.MO.artist ("name") with key id;
create text index on ZITGIST.MO.artistalias ("name") with key id;
create text index on ZITGIST.MO.album ("name") with key id;
create text index on ZITGIST.MO.track ("name") with key id;
vt_batch_update (fix_identifier_case ('ZITGIST.MO.artist'), 'ON', NULL);
vt_batch_update (fix_identifier_case ('ZITGIST.MO.artistalias'), 'ON', NULL);
vt_batch_update (fix_identifier_case ('ZITGIST.MO.album'), 'ON', NULL);
vt_batch_update (fix_identifier_case ('ZITGIST.MO.track'), 'ON', NULL);
VT_INC_INDEX_DB_MO_artist ();
VT_INC_INDEX_DB_MO_artistalias ();
VT_INC_INDEX_DB_MO_album ();
VT_INC_INDEX_DB_MO_track ();
```

Note: Making sure that the graphs and views are deleting to clean Virtuoso from the old definitions

```
SPARQL
drop quad storage virtrdf:MBZROOT.
;

SPARQL
prefix mbz: <http://musibrainz.org/schemas/mbz#>
drop literal class mbz:duration
